1 INTRODUCTION

In the 1930s, the first NMR test samples were inorganic solids such as lithium chloride and potassium fluoride.¹ Unfortunately, NMR spectra could not be obtained from these particular samples because of long spin–lattice relaxation times (the samples were of high purity), and so began the field of NMR of inorganic solids. Fortunately, there have been many successes in the past 50 years. This article is designed to introduce a number of issues pertinent to NMR and inorganic chemistry. It is expected that the section on fluxional organometallic compounds will build on the reader's existing knowledge of NMR. Then, we turn to chemical bonding and NMR, followed by a brief section illustrating the range of applications of NMR to inorganic chemistry.

2 FLUXIONAL ORGANOMETALLIC COMPOUNDS

One of the many interesting aspects of transition metal chemistry is the property of fluxionality. A fluxional transition metal complex can interchange the arrangement of ligands about the metal through an intramolecular mechanism. In some cases, fluxionality will interconnect stereochemical isomers such as trisubstituted amines and also many five-coordinate metal complexes, especially complexes with a trigonal-bipyramidal structure. For commonly observed fluxional processes, the activation barriers range from 10 to 100 kJ mol^{−1}. Measurement of the mode of motion and the activation energy of a fluxional process can give insight into bond formation and bond scission processes that are so critical in catalysis and synthesis. For this reason, the study of fluxional processes has been of great interest, and NMR is the spectroscopic tool most often applied, usually in conjunction with X ray crystallography. The combination of a static structural model and the dynamic information from solution state and solid state NMR is usually enough to define the fluxional process.

2.1 Cyclooctatetraene

It is interesting to consider the motion of a large ligand such as cyclooctatetraene, C₈H₈ (COT), bound to a single metal atom or a multinuclear metal complex. On one hand, the four double bonds of the COT ligand lead to a large ligand cluster binding energy. On the other hand, delocalization of the double bonds can render each carbon site in the COT ligand electronically equivalent. These two conditions lead to a ligand that exhibits fluxionality over a wide temperature range; the low activation barrier allows motion at low temperatures, and the high binding energy prevents decomposition until high temperatures are reached.

The chemistry of COT with iron and ruthenium carbonyls is extensive, and monometallic and multinuclear complexes can be made. From an NMR viewpoint, COT iron carbonyl complexes are interesting since the hydrogen nuclei in the COT ligand comprise the only significant NMR spin system. There is strong dipolar coupling in the proton spin system leading to a homogeneously broadened lineshape. The linewidth and spin–lattice relaxation rate are a function of COT reorientation, thus making solid state proton NMR spectroscopy a useful probe of COT fluxionality.

In 1976, Fyfe and co-workers reported ¹H *T*₁ and *T*_{1ρ} studies for several complexes: (COT)Fe(CO)₃, (COT)[Fe(CO)₃]₂, (μ-COT)(μ-CO)[Fe(CO)₂]₂, and (μ-COT)₂[Ru₃(CO)₄].² In this work, spin–lattice relaxation rates, both in the laboratory frame and in the rotating frame, are dominated by proton dipolar interactions, and the modulation of these interactions by molecular motions; the motions are described by a correlation time, *τ*_c. With these conditions, *T*₁ is given by

$$\frac{1}{T_1} = C \left[\frac{\tau_c}{1 + \omega_0^2 \tau_c^2} + \frac{4\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right] \quad (1)$$

The correlation time is assigned to a thermally activated process and is modeled by an Arrhenius equation:

$$\tau = \tau_0 \exp(E_a/RT) \quad (2)$$

The parameter *ω*₀ is the resonant frequency of the ¹H NMR experiment in units of radians per second, and *C* is an empirically determined constant. A plot of log(*T*₁) versus 1/*T* yields a V shaped curve; the minimum occurs at *ω*₀*τ*_c = 0.62, as shown in Figure 1. Two different strategies were used to change the resonant frequency so that widely different correlation times could be measured. In some cases, the ¹H *T*₁ was measured at two different applied field strengths corresponding to Larmor frequencies of 5.3 and 14 MHz; and also the ¹H *T*_{1ρ} was measured with a spin lock pulse sequence.

The complex with the lowest activation barrier is (μ-COT)(μ-CO)[Fe(CO)₂]₂. The molecular structure and experimental results are shown in Figure 1. The fit of the *T*₁ data to equation (1) and *T*_{1ρ} to a similar relationship yields an activation barrier of only 9 kJ mol^{−1} for the fluxional process. While the ¹H *T*₁ NMR experiment does not yield any definitive information about the mode of motion, the solution ¹H NMR spectra have been interpreted as due to a series of 1,2-shifts of a metal atom around the cyclooctatetraene ring. In summary, solid state ¹H NMR is shown here to be an effective probe of molecular motion over a wide range of correlation

Figure 1 A plot of ^1H T_1 and $T_{1\rho}$ for $(\mu\text{-COT})(\mu\text{-CO})[\text{Fe}(\text{CO})_2]_2$ as a function of inverse temperature. The ^1H T_1 data were collected at a Larmor frequency of 14 MHz. The ^1H T_1 data were fitted to equation (1), and the $T_{1\rho}$ data to a similar equation, yielding an activation energy of 9 kJ mol^{-1} . (Reproduced by permission of the American Chemical Society from Campbell et al.²)

times. It is curious that the activation barrier to rotation can be as small as 9 kJ mol^{-1} . One can conclude that the metal–ligand bonding has little angular dependence and that few lattice interactions have the necessary symmetry to create a significant steric effect. In addition to ^1H NMR, relaxation data for other $S = \frac{1}{2}$ nuclei such as ^{19}F in xenon tetrafluoride have been used to study molecular motion.³

Even though the ^1H T_1 NMR experiment is quite informative, there are some unresolved issues. As mentioned above, the mode of motion is not revealed, be it exclusively 1,2-shifts or a combination of 1,2 and higher order shifts. Also, molecular motion may be occurring elsewhere in the molecule, for example bridging-terminal carbonyl exchange. To address these issues, other NMR experiments may be employed.

2.2 Arene/Ethene

The triosmium arene/ethene complex $\text{Os}_3(\text{CO})_8(\eta^2\text{-CH}_2\text{CH}_2)(\mu_3\text{-}\eta^2\text{-}\eta^2\text{-}\eta^2\text{-C}_6\text{H}_6)$ has been studied by solid state ^{13}C CP MAS NMR.⁴ Previous solution NMR experiments showed an incredible five independent fluxional processes, as summarized in Figure 2: (a) alkene rotation, (b) arene rotation, (c) turnstile rotation of the $\text{Os}(\text{CO})_3$ moieties [the $\text{Os}(\text{CO})_3$ moieties that are *cis* and *trans* with respect to the $\text{Os}(\mu\text{-CH}_2\text{CH}_2)(\text{CO})_3$ moiety have slightly different coalescence temperatures], and

Figure 2 Fluxional processes deduced from solution state NMR of $\text{Os}_3(\text{CO})_8(\eta^2\text{-CH}_2\text{CH}_2)(\mu_3\text{-}\eta^2\text{-}\eta^2\text{-}\eta^2\text{-C}_6\text{H}_6)$. (Reproduced by permission of the American Chemical Society from Heyes et al.⁴)

(d) a trigonal-twist process for the $\text{Os}(\mu\text{-CH}_2\text{CH}_2)(\text{CO})_3$ moiety. To study fluxional processes in the solid state, the ^{13}C CP MAS NMR spectra were acquired with significant variations of experimental parameters. For the aromatic and ethene resonances, the spectra were acquired as a function of the ^1H decoupling field strength, as a secondary test of ligand motion; broader resonances were observed when the Larmor frequency of the ^1H decoupling field matched the rate of ligand motion. Also, the ^{13}C CP MAS spectra were acquired at two different spin rates to yield high-resolution spectra and spectra with extensive spinning sideband patterns. The high-resolution spectra were modeled with a lineshape analysis program to extract exchange rates between sites with different chemical shifts. The spinning sideband patterns of the low-temperature

spectra, especially the carbonyl resonances, were used to verify that indeed a low-temperature limit had been reached; the patterns were analyzed and compared with known chemical shift tensors of static carbonyl systems.

Over the temperature range of 219–335 K, five fluxional processes were observed, and four of these matched the previous solution state processes. Not observed in the solid state was the trigonal-twist process of the $\text{Os}(\mu\text{-CH}_2\text{CH}_2)(\text{CO})_3$ moiety [see process (d) in Figure 2]. The activation barriers for benzene and ethene ligand reorientation in the solid state are very similar to the solution state values. Evidently, the trigonal-twist process is sterically demanding in the solid state.

2.3 Bent Nitrosyl Ligand

The spinning sideband patterns in an MAS NMR experiment can provide information about a fluxional process that is inaccessible in solution state NMR. The ^{15}N CP MAS spectrum of a bent nitrosyl ligand clearly demonstrates fluxionality that most probably exists in the solution state, but is practically impossible to study except in the solid state.⁵ The square-pyramidal complex *meso*-tetraphenylporphinato(nitrosyl) cobalt(III), $[\text{Co}(\text{NO})(\text{TPP})]$, has a nitrosyl ligand in the apical position, as shown in Figure 3. From the X-ray crystallographic work, and with the assumption of fourfold disorder, the $\angle\text{CoNO}$ is 128.5° (in addition to the fourfold disorder, there is also twofold disorder across the basal plane). The fourfold disorder gives the average structure C_{4h} symmetry, and the potential fluxional process, interchange of the nitrosyl ligand among the four sites, is difficult to study by most spectroscopic techniques. However, the ^{15}N chemical shift anisotropy provides a clever route for solid state NMR techniques.

Slow speed ^{15}N CP MAS spectra acquired at 200 K of a ^{15}N -enriched sample of $[\text{Co}(\text{NO})(\text{TPP})]$ show a spinning sideband pattern which, based on a Herzfeld–Berger analysis, is due to ^{15}N chemical shift elements characteristic of a static nitrosyl ligand. In particular, the nitrosyl chemical shift tensor in $[\text{Co}(\text{NO})(\text{TPP})]$ does not have axial symmetry, and the tensor elements correspond to that of model nitrosyl compounds believed to have nonfluxional nitrosyl ligands. On warming $[\text{Co}(\text{NO})(\text{TPP})]$ to 260 K, the slow speed ^{15}N CP MAS spectrum changes markedly, yielding a spinning sideband pattern characteristic of an apparently axially symmetric chemical shift tensor. The change is attributed to motional averaging of the chemical shift tensor. A simple model for the motionally averaged chemical shift tensor yields an estimate for $\angle\text{CoNO}$ of 127° , in very good agreement with the X ray crystallographic result. Unfortunately, the model for the ^{15}N spinning sideband pattern does not yield a measure for the rate of motion of the nitrosyl ligand among the four sites.

2.4 Copper Chemical Vapor Deposition

In the fluxional processes discussed thus far, the site populations are determined by statistics since there is no significant change in the free energy of the system among the different conformers. If, however, the fluxional process leads to conformers with differing free energies, the site populations are determined by the equilibrium constant(s), and the analysis

Figure 3 A partial representation of the molecular structure of $[\text{Co}(\text{NO})(\text{TPP})]$ showing the disorder of the nitrosyl ligand. (Reproduced by permission of the American Chemical Society from W. R. Scheidt and J. L. Hoard, *J. Am. Chem. Soc.*, 1973, **95**, 8281)

becomes more difficult. A successful analysis leads to a rather detailed understanding of the potential energy surface governing the fluxional process. Since potential energies of bond formation and dissociation are important in many fields, the study of complex fluxional processes can generate results with applications to seemingly unrelated subjects, for example chemical vapor deposition.

From an inorganic chemist's perspective, chemical vapor deposition (CVD) requires a metal complex with fluxional ligands—in fact, the ultimate in fluxionality.⁶ Copper(I) complexes have been considered for CVD under two conditions, with and without added hydrogen:

where hfac is 1,1,1,5,5,5-hexafluoro-2,4-pentadionate, and COD is 1,5-cyclooctadiene. The added hydrogen increases the rate of CVD, but the single reactant process is, at this writing, easier to control. For both reactions, the first step is believed to be loss of COD from the copper(I) complex, so it becomes useful to measure the Cu–COD bond dissociation energy. It is already known that the activation energy, based on copper film growth rate, for CVD with $(\text{hfac})\text{Cu}(\text{COD})$ as

Figure 4 Representation of the structure of (hfac)Cu(COD) and the two-site disorder of the copper atom. (Reproduced by permission of the American Chemical Society from Kumar et al.⁶)

the precursor ranges from 109 to 125 kJ mol⁻¹. Admittedly, one would not normally employ a solid state technique such as NMR to study a process like CVD. In fact, early NMR interest was drawn to the molecule because of unusual aspects of its molecular structure as determined by variable temperature X-ray crystallography. The solid state structure showed two-site disorder of the copper atoms, as illustrated in Figure 4. The variable temperature ¹³C CP MAS of (hfac)Cu(COD) shows two resonances for the alkenic carbons at 190 K that coalesce to a single resonance by 340 K. The two resonances were assigned to alkenic carbons bound and not bound to the copper atom. Motion of the copper atom between the two sites, labeled η^2 and $\eta^{2'}$, interchanges the sites involved in copper–oxygen bonding. For this fluxional process, the NMR results could not be used to measure the relative populations of the copper sites, even though the rate of interchange was measured. The X-ray crystallographic data yields the copper site population, and the combination of the two techniques leads to the proposed double-minimum potential energy surface. The minima of the two potential energy wells are about 0.06 nm apart and differ in energy by 3–5 kJ mol⁻¹. The barrier connecting the two conformers is about 60 kJ mol⁻¹. This value is less than the activation energy for Cu CVD but is similar to that reported from temperature-programmed-desorption work for

(hfac)Cu(COD) absorbed on Cu(100) where the activation energy is 59 kJ mol⁻¹.

2.5 Cyclopentadienyl Rotation

Recently, solid state ²H NMR has been used to monitor fluxional processes. Briefly, ²H NMR offers several advantages: a much wider range of rate constants can be measured than is possible from NMR of $S = \frac{1}{2}$ nuclei; the mode of motion is revealed in the solid state ²H NMR lineshape; and selective labeling of sites with deuterium offers great practical advantages.

The motion of the cyclopentadienyl ligand (Cp) in (μ -CO)₂[FeCp(CO)]₂ has been studied by solid state ²H NMR over the temperature range of 100–300 K.⁷ Over this range, the ²H NMR lineshape is constant, always in the fast exchange limit. The good ²H NMR signal-to-noise ratio for the ~70% deuterated Cp ring permits inversion–recovery experiments, and the ²H T_1 was also measured from 100 to 300 K. The ²H T_1 is anisotropic; somewhat different values were measured for the parallel and perpendicular singularities in the spectrum. Also, the anisotropy is evident in both the experimental inversion–recovery spectra and the corresponding lineshape simulations; the rate constant for Cp ring rotation was determined via the lineshape simulations. The mode of motion in the simulations was assigned as jumps among nearest neighbor sites, C₅ jumps. A test of this mode of motion was done by observing the ²H T_2 anisotropy in a series of spectra acquired with different quadrupole echo refocusing times; the simulations for C₅ jumps agreed much better than did simulations for C₅² jumps, jumps to next-nearest neighbor sites. The activation energy for the C₅ jumps is only 12.5(3) kJ mol⁻¹.

2.6 Cyclopentadienyl Motion

In the case of an organometallic salt, ferrocenium hexafluorophosphate, [Cp₂Fe][PF₆], the ²H T_1 could not be used to determine Cp ring motion because of the fast paramagnetic relaxation from the iron center.⁸ Nevertheless, the ²H NMR lineshape was quite informative because of a dramatic change occurring at a first-order phase transition at 347 K. X-ray crystallography of [Cp₂Fe][PF₆] in the low-temperature phase shows disorder, presumably static, among the ferrocenium cations, and the disorder increases in the high-temperature phase. The ²H NMR spectra, combined with calorimetry, indicate that the transition at 347 K is from a low-temperature static disorder to a high-temperature dynamic disorder. The ²H NMR lineshape changes remarkably (Figure 5), indicating extensive motion in the high-temperature phase. However, the motion of the ions in the crystal lattice is somewhat restricted since the entropy gain indicates not all possible mutual orientations of Cp₂Fe⁺ and PF₆⁻ are accessible, probably due to steric interactions.

3 QUADRUPOLEAR AND CHEMICAL SHIFT INTERACTIONS AND CHEMICAL BONDING

Chemical bonding in organometallic and inorganic chemistry is highly variable. Bonds can be as seemingly weak as a

Figure 5 Variable temperature solid state ^2H NMR spectra of $[\text{Cp}_2\text{Fe}][\text{PF}_6]$. At 344 K and below, there is rapid Cp ring rotation but no fast reorientation of the Cp_2Fe^+ complex. (Reproduced by permission of the American Chemical Society from Webb et al.⁸)

metal to η^2 -dihydrogen, to bonds as complex as the quadrupole bond in octachlorodirhenate, $\text{Re}_2\text{Cl}_8^{2-}$. Given this wide range of bonds, many spectroscopic and other characterization techniques are used by inorganic chemists. Of course, X-ray crystallography is probably the premier technique, but NMR and NQR spectroscopy have also played a role in bonding characterizations. In this discussion, the quadrupolar interaction will be emphasized, followed by brief coverage of the chemical shift interaction.

3.1 Quadrupolar Interaction

Deuterium, because it lacks occupied orbitals with angular momentum (p, d, f), is the easiest spin system with which to begin our study of the quadrupolar interaction. The jargon of deuterium NMR and NQR spectroscopy includes the following terms: electric field gradient tensors, nuclear electric quadrupole moments, quadrupole coupling constants, and asymmetry parameters. If we first examine a collection of experimental values of the quadrupole coupling constant for deuterium bound to another atom, for example, atoms of the first and second row, we note a regular pattern, as shown in Figure 6.⁹

3.2 Progression of Electrostatic Interactions

For the purpose of understanding the properties of electric field gradients and electric quadrupole moments, it is helpful to place these terms in a linear progression used to describe any arbitrary electric charge distribution. Let us start with the

Figure 6 Deuterium quadrupole coupling constants for a deuteron bound to another atom; the HD molecule, the LiD molecule, etc. All data shown are for terminal X–D bonds; a deuteron in a bridging bond will have a considerably different value of the quadrupole coupling constant. (Reproduced by permission of Gordon and Breach from Butler and Keiter⁹)

electric quadrupole moment and its place in a progression used to model the charge distribution, $\rho(\mathbf{r})$, of a nucleus:

$$\rho(\mathbf{r}) = Z + \boldsymbol{\mu} \cdot \mathbf{r} + Qr^2 + \dots \quad (5)$$

For atomic nuclei, one is already familiar with the concept of a nuclear charge, Z , while the notion of an atomic electric dipole moment, $\boldsymbol{\mu}$, is distinctly unfamiliar. Of course, molecular electric dipole moments are often encountered in spectroscopy and molecular modeling; important for this discussion is the fact that the electrostatics are the same for both atomic and molecular dipole moments. That brings us to the nuclear electric quadrupole moment, Q , which can be nonzero if the nuclear spin angular momentum is greater than $\frac{1}{2}$. Similarly, electric charges surrounding the nucleus create electric fields that can be described by the following progression: electric potential, electric field, electric field gradient, and higher order terms. The electric potential and field are mathematically described by a scalar and a vector, respectively; the electric field gradient is expressed as a tensor.

There are some specific aspects of the electrostatic interactions that are pertinent for nuclei in atoms and molecules. First, a nucleus, even though surrounded by many electric charges, is always situated in space such that the electric field at the nucleus is zero. If the electric field happens to be nonzero, the nucleus experiences a force that pushes it to a region of zero electric field. Second, the nuclear electric dipole moment is required to be zero based upon the symmetry of the nuclear wave function; a nonzero dipole moment violates time reversal symmetry arguments. Third, the trace of the electric field gradient tensor at a nucleus is zero; additional details about the trace will be given below. Fourth, accurate values of Q are known for some nuclei but not others; a variety of measurement techniques are employed depending upon nuclear spin and atomic electron configuration. Pyykkö has recently summarized values of Q for the first 20 elements.¹⁰ For deuterium, $Q = 2.86 \times 10^{-31} \text{ m}^2$.

3.3 The Electric Field Gradient Tensor

A tensor is a 3×3 matrix that is useful for describing an interaction that has a directional dependence.¹¹ For deuterium in a C–D bond, we find that the electric field gradient along the C–D bond is larger than for a direction perpendicular to the C–D bond.^{12,13} Tensor orientations are expressed relative to an axis system, and there are several axis systems of note. The molecular axis system is preferred for analyzing the results of molecular orbital calculations, while the laboratory axis system has its place in the NMR experiment for defining the orientation of static and rf magnetic fields. However, we will start with yet another axis system called the principal axis system. One feature of the principal axis system is that the 3×3 matrix is diagonal; all off-diagonal elements are zero. The electric field gradient tensor in the principal axis system is

$$\mathbf{V}^{\text{PA}} = \begin{bmatrix} q_{xx} & 0 & 0 \\ 0 & q_{yy} & 0 \\ 0 & 0 & q_{zz} \end{bmatrix} \quad (6)$$

where q is an electric field gradient component. A second feature of the principal axis system is a convention for ordering the diagonal elements of the electric field gradient tensor. By convention, the largest element (magnitude) is defined as the component along the z axis of the principal axis system, and the second largest element as the component along the y axis; thus

$$|q_{zz}| \geq |q_{yy}| \geq |q_{xx}| \quad (7)$$

We noted above that the trace of the electric field gradient tensor is zero, therefore the following relationship holds:

$$q_{xx} + q_{yy} + q_{zz} = 0 \quad (8)$$

Since the trace is zero, only two parameters are needed to describe the electric field gradient tensor in the principal axis system. Based on the NMR Hamiltonians, ‘size’ and ‘shape’ are expressed, respectively, by the quadrupole coupling constant, $e^2 q_{zz} Q/h$, and the asymmetry parameter, η ,

$$\eta = \frac{q_{xx} - q_{yy}}{q_{zz}} \quad (9)$$

The term $e^2 q_{zz} Q/h$ is somewhat lengthy, so it is often represented by either C_Q or χ ; the latter will be used herein. For the convention given in equation (7), the value of the asymmetry parameter ranges from 0 to 1. For $\eta = 0$, the two minor elements q_{xx} and q_{yy} are equal, and have a value of $-\frac{1}{2}q_{zz}$. NMR and NQR experiments yield values for the quadrupole coupling constant and the asymmetry parameter. A few experiments, single crystal NMR and microwave spectroscopy, also yield the orientation of the electric field gradient tensor with respect to the molecular axis system.

At this point, we can use symmetry arguments to predict values, zero or nonzero, for the quadrupole coupling constant χ , and the asymmetry parameter η . First, consider a deuterium nucleus surrounded by six electric charges in an octahedral array, as shown in Figure 7(a). In this high symmetry example, we expect $q_{xx} = q_{yy} = q_{zz}$. If this is so, and since

(a) Octahedral symmetry: $\chi = 0$ kHz, $\eta = 0$

(b) Axial symmetry: $\chi \neq 0$ kHz, $\eta = 0$

(c) Low symmetry: $\chi \neq 0$ kHz, $\eta \neq 0$

Figure 7 Some special electric field gradient tensors for common deuterium sites in molecules and solids. The values of the quadrupole coupling constant and the asymmetry parameter are obtained by symmetry and from equations (7) and (8). (Reproduced by permission of Gordon and Breach from Butler and Keiter⁹)

equation (8) requires the sum of the three elements to be zero, then it follows that all elements must be equal to zero. Hence, $\chi = 0$ and $\eta = 0$ for the deuteron in Figure 7(a). Likewise, a deuteron at a site with T_d symmetry will have zero values for χ and η . (One may wish to consult a text on group theory and note the similarity between T_d and O_h point groups insofar as the transformation of the x , y , and z axes.) Interestingly, χ and η are zero for the gas phase species, D^+ , $D^\cdot$, and D^- ; the quadrupolar interaction does not directly depend upon charge at deuterium when the charge resides in the deuterium centered, spherically symmetric s orbital.

As we move to metal hydride complexes, symmetry arguments also require that η is zero in M–D and linear M–D–M systems [Figure 7(b)]. In these cases, the axial symmetry requires that the two elements perpendicular to the M–D–M axis are equal. If the third element has a different value, and it usually does, then it must be labeled as q_{zz} to satisfy equations (7) and (8). In fact, η will be zero if there is C_3 or higher symmetry at the deuteron. For nonlinear M–D–M bonds [Figure 7(c)], the values of χ and η can be nonzero.

For the purpose of assessing the importance of nuclear charge, we can calculate the nuclear contribution to the electric field gradient at deuterium in an axially symmetric C–D bond of length 0.1095 nm (2.0693 au). Because of the symmetry [Figure 7(b)], η is zero and we need only calculate the field gradient along the z axis (principal axis system; z aligned with the C–D bond, $Z_n = +6$ au):

$$q_{zz}^{\text{nuclear}} = + \sum_n Z_n \frac{3z_n^2 - r_n^2}{r_n^5} = 1.3544 \text{ au} \quad (10)$$

Based on equations (7) and (8), the other elements of the electric field gradient in the principal axis system are

$$q_{xx} = q_{yy} = -\frac{1}{2}q_{zz} \quad (11)$$

again making use of $\eta = 0$.

The conversion of electric field gradient values into frequency units allows for comparison with experimental data. Of course, the conversion factor requires an accurate value for the nuclear electric quadrupole moment:

$$\chi[\text{Hz}] = e^2 q_{zz} Q / h[\text{Hz}] = q_{zz}[\text{au}] \times \frac{e^2 Q}{4\pi\epsilon_0 a_0^3 h} \quad (12)$$

where the field gradient, q_{zz} , is in atomic units, e is the electric charge in coulombs, ϵ_0 is the vacuum permittivity, a_0 is the Bohr radius in meters, and h is Planck's constant. The value of the conversion factor, based on the currently accepted value of Q for the deuteron, is 672 kHz au⁻¹.

In frequency units, the quadrupole coupling constant (nuclear contribution only) for a deuteron in a C–D bond is +910 kHz. This is considerably larger than the experimentally measured value of the deuteron quadrupole coupling constant of +175 kHz for a typical C–D bond. The conclusion is that the electronic contribution is both negative and slightly smaller in magnitude than the nuclear contribution. At first glance, one might have expected the electronic contribution to have exactly the same magnitude as the nuclear term based on the absence of an overall electric charge. However, the r^{-3} averaging tends to emphasize the charges close to the deuteron (the carbon nucleus) and rapidly reduces the contribution from electron density distant from the deuteron site, e.g. electron density in the other covalent bonds to carbon. For the HD molecule, a similar calculation shows that the nuclear contribution is 404 kHz ($r = 0.079$ nm); χ for the HD molecule is 225 kHz.¹⁴ Again, the nuclear contribution is larger than the electronic contribution.

3.4 C–D Bonds

In principle, the value of χ for a deuteron in an X–D bond should be sensitive to the presence of excess electric charge on X. This principle was applied to a study of charge on carbon in the bridging methylene unit in *cis*-(μ -CD₂)(μ -CO)[FeCpCO]₂.¹⁵ Earlier, a photoelectron study found an abnormally small C_{1s} binding energy; the low binding energy was interpreted by assigning a charge of $-0.5e$ on carbon relative to a model CH₂ unit.¹⁶ A relative charge, Δq , of $-0.5e$ should reduce the value of χ as the shielding of the nuclear charge by the additional valence charge is larger. The problem is deducing the proportionality constant between charge and $\Delta\chi$. One estimate for the value of $\Delta\chi/\Delta q$ comes from a point charge model identical to the calculation, leading to the nuclear contribution to χ for carbon. For a C–D bond length of 0.1095 nm, the six protons of the carbon nucleus generate a field gradient at deuterium corresponding to $\chi^{\text{nuclear}} = +910$ kHz. Since χ^{nuclear} depends linearly upon charge, $\Delta\chi/\Delta q = 152$ kHz e⁻¹, indicating that deuterium NMR should be a very sensitive measure of charge on carbon in the bridging methylene unit. (Actually, a more realistic model for the spatial distribution of the excess charge is used based upon

a carbon 2p atomic orbital; the diffuse charge reduces $\Delta\chi/\Delta q$ to 61.2 kHz e⁻¹.¹⁵) However, χ for the bridging methylene site in *cis*-(μ -CD₂)(μ -CO)[FeCpCO]₂ was not shifted to a lower value, thus indicating a normal charge on carbon relative to the aliphatic model. Interestingly, χ values for other bridging methylene sites do indicate a small negative charge on carbon; perhaps there is a *trans* effect from the bridging carbonyl that operates across the Fe–Fe bond.

3.5 M–D Bonds

For deuterium sites bound to metals, quadrupole coupling constants range from near zero to nearly that of the HD molecule. This wide range of χ values is, in the context of Figure 6, related to the metal nuclear charge, to the shielding by core and valence electrons, and to the wide range of M–D bond lengths. In addition, unusually symmetric environments can also reduce χ . In stoichiometric PdD, the deuterium sites have local octahedral symmetry, thus χ is near zero.¹⁷ A few systems with terminal M–D bonds have been studied: LiD, 33 kHz;¹⁸ Cp₂MoD₂, 52 kHz;¹⁹ Cp₂WD₂, 54 kHz;¹⁹ DMn(CO)₅, 68 kHz;²⁰ and [Cp₂ZrD₂]_x, 46.7 kHz.²¹ The relatively small values found in terminal M–D bonds are probably due both to a large electronic contribution and to the length of an M–D bond; the χ values are consistent with Salem's correlation between χ and the vibrational force constant.^{21,22} Of all of these values, only that for LiD is known to be positive; χ is likely to be positive for all sites, but there are as yet no experimental data for the other metal hydrides.

Bridging metal hydride bonds have η values that depend upon $\angle\text{MDM}$. The bridging metal hydrides, [DCr₂(CO)₁₀]⁻ and [DW₂(CO)₁₀]⁻, have structures that vary as a function of counterion; asymmetry parameters range from near zero to 0.31.²³ The values of χ and η have been analyzed with a simple point charge model with the assumption that the sign of χ is positive.

Preliminary data and results from molecular orbital calculations of a model system show that χ and η vary in a predictable manner for the η^2 coordination of dihydrogen to a metal site. The model system indicates that χ and η slowly evolve until scission of the dihydrogen bond yields a *cis*-dihydride.²⁴ The limiting χ values are 225 kHz for the D₂ molecule and of the order of 50–80 kHz for the *cis*-dihydride. Kubas et al.²⁵ reported $\chi = 124$ kHz for W(CO)₃(PPR₃)₂(η^2 -D₂), which is in good agreement with both the simple model described herein and the molecular orbital calculations.

3.6 Sign of the Deuterium Quadrupole Coupling Constant

In Figure 6, the sign of χ is positive, and all interpretative models to date are based on a positive value. However, there is some reason to suspect that the sign may be negative for some bridging metal hydride bonds; if so, the model must be improved, particularly for surface science studies. Experimentally, there are few methods for measuring the sign: gas phase microwave spectroscopy²⁶ and NMR spectra, showing both quadrupolar and dipolar interactions,²⁷ are two. Neither of these methods is generally useful in organometallic chemistry. However, at very high magnetic fields and very low temperatures, the Boltzmann distribution of spin state

populations is such that the solid state deuterium NMR lineshape is skewed. The direction of skew, either to low frequency or high frequency, uniquely determines the sign of the deuterium quadrupole coupling constant. Kuhns and Waugh²⁸ recently measured the sign of the ^7Li quadrupole coupling constant²⁹ in LiNO_3 at 5.9 T, and the sign of χ for ^{165}Ho in ferromagnetic gadolinium was reported by Shaw et al.³⁰ Signs of quadrupole coupling constants for some nuclei can be measured in Mössbauer spectroscopy, as has been done for dioxidized biferrocenylene.³¹ The sign of χ for dioxidized biferrocenylene is negative, while for ferrocene it is positive.

3.7 Nitrogen

For nuclei other than hydrogen, the electric field gradient at the nucleus is often a function of the relative population of p orbitals centered on that nucleus. Thus, if the nucleus has an electric quadrupole moment, then NQR spectroscopy can be used to infer information about chemical bonding. A good illustration of this approach is a ^{14}N NQR study by Rubenacker and Brown of pyridine complexes with a range of Lewis acids.³² In the pyridinium complexes, the relative populations of the donor nitrogen p orbital change with Lewis acid; for example, Li^+ accepts practically no charge from nitrogen whereas CH_3^+ accepts more than 0.5 e from the nitrogen lone pair.

A model for atomic orbital populations and NQR spectroscopy was developed in the 1950s, and is known as the Townes–Dailey model. The model, as adapted for pyridine, starts with expressions for the three components of the diagonalized electric field gradient tensor:

$$q_{xx} = [\text{Np}_x - \frac{1}{2}(\text{Np}_y + \text{Np}_z)]q_0 \quad (13)$$

$$q_{yy} = [\text{Np}_y - \frac{1}{2}(\text{Np}_x + \text{Np}_z)]q_0 \quad (14)$$

$$q_{zz} = [\text{Np}_z - \frac{1}{2}(\text{Np}_x + \text{Np}_y)]q_0 \quad (15)$$

where q_0 is the electric field gradient that would be produced by only one electron in a nitrogen 2p orbital. The nitrogen atomic orbital populations are given by Np_x , Np_y , and Np_z . The local site symmetry for the pyridinium complexes is C_{2v} , leading to four hybrid atomic orbitals, written here in terms of 2s and 2p atomic orbital occupancies:

$$a = \text{Np}_y \quad (16)$$

$$b = \frac{1}{2}[\cot^2(\frac{\alpha}{2})]\text{Np}_z + \frac{1}{2}[1 - \cot^2(\frac{\alpha}{2})]\text{Ns} + \frac{1}{2}\text{Np}_x \quad (17)$$

$$\sigma = [1 - \cot^2(\frac{\alpha}{2})]\text{Np}_z + [\cot^2(\frac{\alpha}{2})]\text{Ns} \quad (18)$$

The hybrid orbitals are schematically illustrated in Figure 8, and are defined as follows: parameter a is the population of the nitrogen $p\pi$ orbital, parameter b is the population of nitrogen orbitals in each of the carbon–nitrogen σ bonds, parameter σ is the population of the nitrogen orbital in the σ bond of the Lewis acid–base complex, and α is the $\angle\text{CNC}$. The model development then continues with parameterization for the free pyridine base in which parameter σ is assigned the value of 2.

Figure 8 Coordinate system and nitrogen atomic orbital population parameters for the electric field gradient model of coordinated pyridine. (Reproduced by permission of the American Chemical Society from Rubenacker and Brown³²)

From the experimental quadrupole coupling constant and the asymmetry parameter, the values of e^2q_{xx}/h , e^2q_{yy}/h , and e^2q_{zz}/h are calculated. One should note, however, that the principal axis system is not necessarily as depicted in Figure 8, thus a search is made for the best fit from among the 12 possible principal axis systems. The value of σ , the donor orbital occupancy, is obtained from the fit. For a poor Lewis acid such as Li^+ , $\sigma = 1.947$, and for a strong Lewis acid such as BCl_3 , $\sigma = 1.537$. One of the more extreme values, $\sigma = 1.283$, is found for pyridine N -oxide, where some π bonding is expected in addition to the σ charge donation described in the model. A similar extended Townes–Dailey model was applied to ^{14}N NQR data of divalent metal complexes with anthranilic acid (2-aminobenzoic acid).³³ This work showed that ^{14}N electric field gradients responded more strongly to the metal atom than did the nitrogen 1s binding energy, making NQR a more sensitive probe of metal–ligand bonding.

The interpretation of NQR data for transition metals is more complicated than for ^{14}N , and some of the models are similar to those used in Mössbauer spectroscopy. It has proved relatively easy to acquire ^{59}Co NQR spectra on several series of cobalt complexes, including the six-coordinate bis(dimethylglyoximate)cobalt(III) complexes.³⁴ The two dimethyl-glyoximate ligands form a planar array of nitrogens, leaving the remaining two axial sites accessible to ligands such as methyl, chloro, and triphenylphosphine. As the axial ligands are varied, the NQR parameters change considerably, and, based on the model, the principal axis system undergoes several reorientations. The model is based on partial field gradients and has parameters that represent the electric field gradient induced at the cobalt nucleus by each of the ligating atoms. The model fits the spectroscopic data for 27 cobalt complexes and shows that the amount of charge donation by the dimethylglyoximate ligand is not constant but is affected by the nature of the axial ligands.

3.8 Oxygen

The reversible binding of dioxygen to a metal center, as for hemoglobin and myoglobin, is an area where the study of

^{17}O sites could be useful. However, it is exceedingly difficult to acquire an ^{17}O NQR spectrum in these systems. Lumpkin and co-workers built a fast field cycling spectrometer and successfully acquired the ^{17}O NQR spectrum of dioxygen bound to Vaska's complex, $\text{IrO}_2\text{Cl}(\text{CO})[\text{P}(\text{C}_6\text{H}_5)_3]_2$, by operating at 4.2 K.³⁵ Two oxygen sites were resolved, both with quadrupole coupling constants near 16 MHz. Unfortunately, the parameters were not further developed into a model of dioxygen bonding, even though later experimental work yielded spectra for oxyhemoglobin.

3.9 Rhenium

There have been relatively few NQR reports for metals such as rhenium in the third row of the transition metal series. Even so, the available data show that surprising results may be found. The complex dirhenium decacarbonyl $\text{Re}_2(\text{CO})_{10}$ has approximate D_{4d} molecular symmetry in the crystalline phase, and so one might expect an asymmetry parameter near zero. Interestingly, NQR spectroscopy at room temperature and 77 K yields $\eta = 0.63(3)$ and $\eta = 0.88(3)$, respectively.³⁶ One explanation that has been offered starts with the equatorial carbonyls and the extreme sensitivity of the rhenium site to small distortions. In fact, more recent X-ray crystallographic work shows that Re–C bond lengths vary from 0.1973(6) to 0.2007(6) nm.³⁷ Furthermore, the radial distribution function for the rhenium 5d wave function is so diffuse that even variations in the C–O bond length may be transmitted to the electric field gradient at the rhenium nucleus.

3.10 Chemical Shifts and Bonding

The chemical and physical properties of bridging methylene metal dimers are fascinating.³⁸ With a hydride acceptor, $(\mu\text{-CH}_2)(\mu\text{-CO})[\text{FeCp}(\text{CO})]_2$ can be converted to a bridging methine metal cation; treatment with a noncoordinating acid yields an agostic methyl bridged cation. In a molecular orbital picture of the bonding between a CH_2 unit and the metal dimer, the salient features are carbon based σ donating a_1 and π accepting b_1 valence orbitals interacting with metal based orbitals. With the presence of low lying metal–carbon antibonding orbitals, one can anticipate an unusual ^{13}C NMR chemical shielding interaction. The isotropic chemical shift is 145.6 ppm, showing substantially more paramagnetic shift than most organic methylene units with isotropic chemical shifts of 20–30 ppm.

An analysis of the paramagnetic contribution to the carbon chemical shift in the bridging methylene unit is quite interesting on several counts. First, the local C_{2v} site symmetry simplifies the molecular orbital picture as the carbon atomic p orbitals correspond to separate and easily identifiable molecular orbitals. Second, the bonding about the carbon site varies widely. The C–H bonds are expected to be strong, with a bond dissociation energy of the order of 430 kJ mol^{-1} . However, the C–Fe bonds should be much weaker, of the order of 200 kJ mol^{-1} . These two factors yield closely spaced occupied and empty molecular orbitals involving two, and only two, of the carbon atomic p orbitals. And, based on the angular momentum operators for the paramagnetic chemical

shift interaction, a large shift is expected perpendicular to the plane defined by the Fe_2C metallocyclopropane unit. The results of the ^{13}C CP MAS and ^{13}C nonspinning NMR experiments yield a chemical shift tensor with two relatively normal tensor elements, 82 and -18 ppm (TMS), and one extraordinarily large element of 372 ppm that is perpendicular to the Fe_2C plane. In summary, the distinctive feature of the bridging methylene unit in a metal dimer or cluster is the remarkable range of chemical bonds to the carbon site, which is then reflected in the chemical shift tensor.

A similar analysis of the chemical shift tensor was attempted for the square-planar tetracyanometalates ($\text{M} = \text{Ni}, \text{Pd}, \text{Pt}$).³⁹ Surprisingly, there are only small differences in the tensor elements on going from nickel to platinum, and all of the chemical shift tensors are rather similar to that of acetonitrile. Since other information suggests that the metal–cyanide bond strength increases from nickel to platinum, the constancy of the chemical shift tensor is unexpected. Bonding and electronic conduction properties were the motivating factors in a study by Vaughan and co-workers of the one-dimensional conductor $\text{K}_2\text{P}(\text{CN})_4\text{Br}_{0.3} \cdot 3\text{H}_2\text{O}$, a Krogmann salt.⁴⁰ The room temperature ^{13}C NMR spectrum shows some asymmetry about the C–N bond in accord with conduction along the stacking axis; the chemical shift along the conduction axis is 187 ppm (TMS), while perpendicular to the stacking axis the shift is 225 ppm. One might expect the metal center to be more affected by conduction. Indeed, the ^{195}Pt T_1 and T_2 show evidence of charge density waves below the metal–insulator transition.⁴¹ The orientation of a chemical shift tensor is also of importance in ^{31}P NMR where a series of cyclic bidentate phosphine complexes have been studied.⁴² In the model developed for the four- to seven-membered chelates, the ^{31}P chemical shift tensor orientation rotates smoothly and is correlated with $\angle\text{MPC}$.

4 A FEW EXAMPLES OF SOLID STATE NMR AND INORGANIC SOLIDS

Presented here are examples that build upon the principles and concepts given earlier. As a convenience to the reader, the examples are arranged by atomic number, though admittedly there are many other possible arrangements.

4.1 Hydrogen-2

The ability to follow motional processes even in paramagnetic solids is highly useful. In the business of environmental management, hazardous wastes such as phenol are mixed with Portland cement for the purpose of solidification/stabilization. While the material appears solid, and other evidence indicates complete deprotonation of the phenol and formation of calcium salts, it is the technique of solid state ^2H NMR that allows one to monitor the phenol over the cement cure time.⁴³ Unfortunately for solidification/stabilization, after 1 year cure, only 55% of the phenol is actually bound to the cement matrix (as measured by the fraction executing 180° ring flips). The remaining phenol fraction is freely mobile.

4.2 Carbon-13

Transition metal complexes of carbon suboxide ($\text{O}=\text{C}=\text{C}=\text{O}$) are highly reactive and difficult to characterize. Hillhouse and co-workers prepared $(\text{PPh}_3)_2\text{Ni}(\text{C},\text{C}':\eta^2\text{-C}_3\text{O}_2)$ from selectively isotopically enriched carbon suboxide and obtained ^{13}C CP MAS NMR spectra.⁴⁴ The chemical shifts of the carbon suboxide ligand are distinctive and shift on coordination to nickel; also, the ^{13}C resonance *trans* to a phosphine shows *J* coupling, enabling identification of the mode of coordination of carbon suboxide.

Silica-supported $\text{Os}_3(\text{CO})_{12}$ represents a large range of catalysts used in petroleum refining. In an extensive project by Shapley, Oldfield, and their co-workers, ^{13}C MAS NMR spectroscopy was used to study physisorbed $\text{Os}_3(\text{CO})_{12}$ as well as to characterize reaction products such as chemisorbed $\text{HOs}_3(\text{CO})_{10}(\text{OSi}\equiv)$.⁴⁵

Fullerene- C_{60} (C_{60}) provides an interesting application of non-sample-spinning ^{13}C NMR spectroscopy. At 295 K, a single narrow resonance at 143 ppm is observed for solid C_{60} .⁴⁶ On cooling to 77 K, a chemical shift powder pattern is seen with components at 220, 186, and 40 ppm, consistent with the aromatic sites in C_{60} and facile rotation of the molecule in the solid state.

4.3 Fluorine-19

The intercalation of small molecules into layered structures⁴⁷ such as graphite, montmorillonite, and zirconium hydrogen phosphate is a field in which NMR is used extensively. The process of AsF_5 intercalation into graphite was monitored as a function of time by one-dimensional ^{19}F NMR imaging; the single narrow ^{19}F resonance simplifies the imaging experiment nicely.⁴⁸

4.4 Sodium-23

Sodium is an important charge balancing cation in zeolites, and, thus, should be intimately involved when other charge species are introduced into the zeolite structure. Molybdenum and tungsten hexacarbonyls can be sorbed by sodium zeolite Y, then photo-oxidized with dioxygen. The ^{23}Na double rotation NMR (DOR) spectrum shows sufficient resolution, based on isotropic chemical shifts, that changes can be seen as the metal carbonyl is oxidized.⁴⁹

4.5 Aluminum-27

Portland cement is a complex material and has been difficult to study well by NMR. Recently, Skibsted et al. made remarkable progress with high speed ^{27}Al MAS NMR and computer simulations of the ^{27}Al spinning sideband pattern.⁵⁰ The different phases are resolved based on chemical shift, quadrupole coupling constant, and asymmetry parameter. The relative concentration of several calcium aluminate and aluminates hydrates were measured as a function of cement cure.

Recently, magnetic field swept ^{27}Al NMR has been used to study $\alpha\text{-Al}_2\text{O}_3$ and hydrogen faujasites (FAU) zeolites.^{51,52} The advantage of field swept NMR is that it easily allows operation at very low temperatures. The objective is to reduce ion motion and achieve a static limit in the NMR spectrum of the quadrupolar nuclei.

4.6 Silicon-29

The ZSM-5 zeolite has a complex structure, and this structure is also affected by temperature and the presence of sorbed *p*-xylene.⁵³ Because of the similarity of all the ^{29}Si sites, the 2D COSY and INADEQUATE experiments yield informative, yet still ambiguous results. Fortunately, a unique spectral assignment is possible with the additional symmetry information provided by X-ray powder diffraction.

4.7 Phosphorus-31

Nonlinear optical materials⁵⁴ can be made from solid solutions of BaLiPO_4 and PbLiPO_4 . The greatest efficiency for the second harmonic generation of 1064 nm radiation occurs for a solid solution with the composition $\text{Ba}_{0.55}\text{Pb}_{0.45}\text{LiPO}_4$.⁵⁵ This composition lies near a structure phase transition, and the ^{31}P chemical shift is also sensitive to the phase transition. The combination of ^{31}P NMR and the Kurtz method for estimating second harmonic generation worked well in the search for the optimum composition.

Two-dimensional NMR techniques are not yet commonly used for inorganic systems, the ^{29}Si COSY and INADEQUATE experiments on zeolites by Fyfe being one of the few examples.⁵³ Wu and Wasylishen have tested and optimized SECSY, COSY, and homonuclear *J* resolved ^{31}P CP MAS NMR techniques for simple metal phosphine complexes.⁵⁶ Given the ubiquity of phosphines in transition metal catalysis, this is a timely contribution.

4.8 Yttrium-89

Yttrium organometallic chemistry ranges from the tetrahydrofuran adduct of Cp_3Y to alkoxide complexes such as $\text{Y}_3[\text{CO}(\text{CH}_3)_3]_7\text{Br}_2(\text{THF})_2$. The NMR of a low gyromagnetic ratio nuclei such as ^{89}Y is somewhat difficult. However, cross polarization from the proton spin system has proven to be effective, and, therefore, ^{89}Y CP MAS NMR is becoming popular for these complexes.⁵⁷

4.9 Niobium-93 and Tantalum-181

This article started with a negative result, and will end with another sad story. A series of M_2X_{10} complexes ($\text{M} = \text{Nb}, \text{Ta}$; $\text{X} = \text{Cl}, \text{Br}$) were studied by NQR in 1973 by McCarley and co-workers.⁵⁸ At the time, single crystal X-ray crystallography was not the routine experiment that it is today, and alternative structural characterization methods were examined. Unfortunately, while numerous transitions were observed, the NQR method did not prove to be a simple or straightforward structural identification method and this branch of chemistry appears to have been discontinued.

1 INTRODUCTION

Intercalation compounds are formed by the reversible insertion of guest species into solid matrices which retain their structure except for certain lattice expansions. They may be considered as a subclass of inclusion compounds, a term that has been used for a larger group of materials consisting of host and guest species. For intercalation reactions an increasing number of host lattices with different structural dimensionality is nowadays available ranging from insulators such as layered silicates to semiconductors and metallic conductors, e.g. graphite, transition metal dichalcogenides, or molybdenum cluster compounds. The guest species include small atomic ions as well as solvated systems and larger molecular units. As far as the aspects of the materials, the preparation of the compounds, and other chemical and physical properties are concerned, we have to refer to review articles and monographs which cover a broader horizon and some specific aspects of the subject.¹ Applications of intercalation compounds comprise battery systems, electrochromic displays, catalysis, and sensors, as well as the employment as model systems for low-dimensional solids.

Solid state NMR studies have contributed substantially to the understanding of the structure and dynamics of intercalation compounds. The location of guest molecules, their orientation and bonding characteristics, guest–host interactions, the donation of electrons to the host, and motions of the intercalated species are some of the problems that have been addressed using NMR. Chemical shift, nuclear quadrupole, and dipole–dipole interactions, and relaxation rates have been utilized to obtain data on the structure and dynamics of intercalation compounds. High-resolution techniques such as MAS or multiple pulse methods were only applied in exceptional cases, since the information on the anisotropy is of major importance. Broadline spectra of compounds with reduced dimensionality are often distinguished by much better resolved structures than those of three-dimensional solids.

Among the materials that have been investigated using NMR techniques, characteristic differences exist between intercalation compounds with insulator host lattices and those which exhibit electronic conductivity. The most important

groups of the first class of compounds are zeolites, pyrochlores, sheet silicates, and β -alumina, which are generally discussed in another context. We will concentrate on host lattices with electronic conductivity, which have attracted increased interest in recent years because of the large diversity of compounds. The intercalation in these materials can be described by the concept of reversible topotactic redox reactions, and is connected with the transfer of electrons entering or leaving the conduction band of the host matrix.

The most important classes of such systems are two-dimensional layered intercalation compounds with cationic or solvated ionic guest species or with intercalated molecules, and three-dimensional framework structures containing channels or cavities for the uptake of small guest species. Among the materials known for a long time, the graphite intercalation compounds belong to the layered systems, and hydrogen bronzes may be formed in both three- and two-dimensional structures.

Within this article it is of course not possible to present a survey of all the NMR results which contributed to the understanding of the structure of intercalation compounds or of the motions of guest species. For this the reader is referred to the literature, and especially to a recent, comprehensive review.² Here it is attempted to illustrate the potential of NMR for the examination of intercalation compounds by means of typical examples. To this aim, in the next section some example techniques and experiments using multinuclear magnetic resonance will be discussed as an introduction to the methods. Section 3 contains more recent NMR studies of some special layered chalcogenide systems, while Section 4 is devoted to molybdenum cluster sulfides, the class of intercalation compounds with a framework structure which was recently investigated in most detail.

2 TYPICAL NMR EXPERIMENTS WITH INTERCALATION COMPOUNDS

2.1 Powder Patterns or Oriented Samples

Optimum information is of course obtained if—in exceptional cases—single crystals are available. Figure 1 shows, as an example, the ^1H NMR spectrum of the metal–ammonia intercalation compound $\text{Na}_x(\text{NH}_3)_y[\text{MoS}_2]$ for the two limiting orientations, where the angle Θ between the crystalline c axis and the external field is either 0 or 90°. The angular dependence follows a $(3 \cos^2 \Theta - 1)$ law. The following information was obtained: (i) the large triplet splitting belongs to the dipolar proton–proton interaction in a rotating three-spin system; (ii) each component is split once more by the interaction with the nitrogen nucleus; (iii) the C_3 axes of NH_3 are oriented parallel to the layer planes; and (iv) there is an additional reorientational motion of the NH_3 molecules about an axis parallel to the hexagonal c axis and perpendicular to the direction of the C_3 axis; this motion becomes frozen at temperatures below about 100 K.

Most investigations refer to powder samples consisting of small crystallites of the material. In conducting layered compounds, as a consequence of the Pauli paramagnetic anisotropy, there is a tendency of the crystallites in sufficiently high magnetic fields to become aligned. Figure 2 shows as an example the ^1H NMR spectra of the hydrated system Na_x

Figure 1 Proton NMR derivative spectra of an $\text{Na}_x(\text{NH}_3)_y[\text{MoS}_2]$ single crystal at 300 K for two orientations of the hexagonal c axis in a magnetic field of 0.19 T. Measurements were made for both intercalated $^{14}\text{NH}_3$ and $^{15}\text{NH}_3$. (Reproduced by permission of Oldenbourg Verlag from E. Wein, W. Müller-Warmuth, and R. Schöllhorn, *Z. Phys. Chem. (NF)*, 1987, **151**, 113)

$(\text{H}_2\text{O})_y[\text{NbS}_2]$ for a loosely packed sample [Figure 2(a)], for a more compact sample [Figure 2(b)], and a sample where the small crystallites were embedded in Teflon powder and pressed into the ampule [Figure 2(c)]. The limiting spectra [Figure 2(a) and (c)] correspond to a normal powder pattern (Pake doublet with anisotropic chemical shift) and a situation where all the crystallites are completely oriented with their hexagonal c axes parallel to the external field.

The magnetic field induced orientation phenomena observed in many solid state NMR experiments of layered compounds can be explained in terms of the magnetic properties and depend on the density of states at the Fermi level of the transition metal chalcogenides or graphites.³ Orientation or partial orientation may lead to misinterpretations of the spectra if not recognized, or we may profit from it by conducting experiments which are otherwise not possible. An example is given in Figure 3. The powder pattern of the ^{93}Nb NMR in the host lattice NbS_2 is broad and can be simulated by chemical shift and quadrupole interactions ($\delta_{\text{iso}} = 1350$ ppm referred to niobium pentachloride, $\Delta\sigma = 4200$ ppm, $\chi = e^2qQ/h = 61$ MHz, $\eta_{\text{CS}} = \eta_{\text{Q}} = 0$). In a loosely packed sample, by contrast, only one narrow, central transition (CT) can be observed in the covered range. However, it is possible to detect

Figure 2 Proton NMR spectra of polycrystalline $\text{Na}_x(\text{H}_2\text{O})_y[\text{NbS}_2]$ observed in a magnetic field of 7 T, whereby the density of the package of the sample was increased from top to bottom

all the eight satellite transitions (ST) of the spin- $\frac{9}{2}$ nucleus as well if the detection range is greatly expanded. The positions of these lines can be reproduced by spectrum simulation with first- and second-order quadrupole interactions, resulting in a very precise determination of the coupling constant.

Intercalation of copper produces a satellite spectrum of 18 lines [Figure 3(c)], which was explained by the superposition of two complete spectra with quadrupole coupling constants of 39.12 and 36.05 MHz instead of 60.02 MHz for the empty host. They belong to two distinct niobium environments in the host lattice with an occurrence ratio 1:1 caused by a well ordered arrangement of copper atoms in tetrahedral sites of the van der Waals gap.

Application of the magnetic field induced orientation effect is in many cases the only way at all to detect and to analyze NMR spectra in layered intercalation compounds. It is often possible to maintain the orientation in a sample by dispersing the crystallites in a resin, and curing the resin after a strong magnetic field had been applied to induce orientation. Angle-dependent measurements are then possible, as shown in Figure 4 for the ^{63}Cu NMR of $\text{Cu}_{0.5}[\text{NbS}_2]$.

2.2 Anisotropic Dynamics of an Intercalated Heteronuclear Four-Spin System

An instructive example from the NMR point of view is difluoromethane. In the presence of larger alkali cations it is possible to intercalate molecules with low solvating power such as CH_2F_2 . Well structured ^1H and ^{19}F NMR spectra were observed (Figure 5) and could be simulated on the basis of a proper model.⁴ They were calculated from the numerical solution of the eigenvalue problem of a Hamiltonian which

Figure 3 Niobium-93 NMR spectra of layered 2H-NbS₂ in a magnetic field of 7 T and 200 K. (a) The powder pattern (sample pressed in Teflon powder) was recorded at $\nu_0 = 73.41$ MHz and superimposed of successively excited contributions (solid echo sequences with pulse lengths below $6\ \mu\text{s}$ and delay times $15\text{--}40\ \mu\text{s}$). (b) For the loosely packed sample, where the crystallites appeared to be completely oriented in the external field, a central transition (CT) at 73.56 MHz and eight satellites (ST) were observed. (c) Upon intercalation, for Cu_{0.5}[NbS₂] a spectrum of 18 lines was recorded (bottom). (Reproduced by permission of Elsevier Science Publishers from Janssen et al.³)

considers, in addition to the two Zeeman terms, 10 further interaction terms: the chemical shift of the four hydrogen and fluorine atoms [where the respective principal axis systems (PASs) are defined by the direction of the C–H and C–F bonds], the two homonuclear dipole–dipole interactions (PASs in the H–H and F–F directions), and the four heteronuclear dipole–dipole interactions (with the PASs given by the various H–F separation vectors).

In order to describe the orientation of a particular CH₂F₂ molecule with respect to the laboratory frame ($z \parallel \mathbf{B}_0$), a molecular fixed coordinate system was defined with its x' axis parallel to the F–F vector and the z' axis in the direction of the H–H vector of the tetrahedral molecule. In the further treatment, the transformation from the PASs of the various interactions to the laboratory frame was then replaced by the two successive transformations from the PASs to the molecular frame (Eulerian angles obtained from the geometry) and from the molecular to the laboratory frame (two Eulerian angles α' and β' appear in the result). Powder patterns result from spatially weighted sums over all possible orientations (α', β') of the CH₂F₂ molecules.

Theoretical NMR spectra were calculated for various chemical shift anisotropies and possible thermally activated reorientations about various axes. The obtained ¹H and ¹⁹F NMR lineshapes were then compared with the experimental

Figure 4 (a) Copper-63 NMR spectrum of Cu_{0.5}[NbS₂] at 79.556 MHz and 210 K detected by the utilization of the field induced orientation of crystallites (solid echo sequences with pulse lengths $5\ \mu\text{s}$, delay $20\ \mu\text{s}$, repetition 0.1 s). The angles on the right-hand side indicate the angle between the c axis and $\mathbf{B}_0$. The satellites are not shown. (b) By computer simulation the following parameters were determined: $\delta_{\text{iso}} = 730$ ppm (relative to CuCl), $\Delta\sigma = -600$ ppm, $\eta_{\text{CS}} = 0$, $\chi = 14.93$ MHz, $\eta_{\text{Q}} = 0.11$; the principal axes of the CS and QF tensors coincide. Additional NMR signals arising from the ⁹³Nb nuclei and from ²³Na probe background are marked in the figure. (Reproduced by permission of Elsevier Science Publishers from Janssen et al.³)

spectra such as those shown in Figure 5. In conclusion, intercalated difluoromethane appears to be oriented with its z' axis (H–H direction) perpendicular to the layer planes, and at 300 K it reorients rapidly about this axis. Another orientation of the intercalated molecules or another type of motion would result in quite different ¹H and ¹⁹F NMR spectra.

2.3 NMR Spectra in the Presence of Various Interactions where the Principal Axes do not Coincide

Interpretation of solid state NMR spectra in the presence of dipole–dipole (DD), chemical shift (CS) and quadrupole (QF) interactions is straightforward if the principal axes of the CS and QF tensors coincide. Appropriate procedures and suitable computer programs have been developed. In two-dimensional intercalation compounds such a requirement is generally met (at least for the guest species), and the axis parallel to the layer planes is in most cases the principal axis for both the CS and QF tensors. The interpretation of the spectra shown in

Figure 5 (a) Proton and (b) fluorine-19 NMR spectra of $\text{Cs}_x(\text{CH}_2\text{F}_2)_y[\text{NbS}_2]$ measured at 30 MHz and 295 K. The magnetic field was sufficiently low to rule out orientation effects of the crystallites. The intense central resonances belong to unreacted difluoromethane molecules in the sample. (Reproduced by permission of Academic Press from Möller et al.⁴)

Figures 3 and 4 were examples of this behavior. Particularly in three-dimensional intercalation compounds, however, it may well be the case that the directions of the PASs do not coincide. An example is the broad and asymmetric ^7Li NMR spectra of the molybdenum cluster chalcogenides $\text{Li}_3\text{Mo}_6\text{X}_8$ ($\text{X} = \text{S}, \text{Se}$) shown in Figure 6.⁵

The lineshape was simulated by the following expression for the transition frequency from a state m to a state, $m - 1$:

$$\begin{aligned} \omega = & \omega_0(1 + \sigma_{\text{iso}}) + \frac{1}{6}\omega_0\Delta\sigma \\ & \times \{3\sin^2\beta\sin^2\vartheta\cos 2\varphi - 3\sin 2\beta\sin 2\vartheta\cos\varphi \\ & + (3\cos^2\beta - 1)(3\cos^2\vartheta - 1) \\ & - \eta_{\text{cs}}[\frac{1}{2}(1 + \cos\beta)^2\sin^2\vartheta\cos 2(\varphi + \gamma) \\ & + \frac{1}{2}(1 - \cos\beta)^2\sin^2\vartheta\cos 2(\varphi - \gamma) \\ & + (1 + \cos\beta)\sin\beta\sin 2\vartheta\cos(\varphi + 2\gamma) \\ & - (1 - \cos\beta)\sin\beta\sin 2\vartheta\cos(\varphi - 2\gamma) \\ & + \sin^2\beta\cos 2\gamma(3\cos^2\vartheta - 1)]\} \\ & + \frac{3e^2qQ}{4I(2I - 1)\hbar}(\frac{1}{2} - m)[3\cos^2\vartheta - 1 \\ & - \eta_Q\sin^2\vartheta\cos 2\varphi] \end{aligned} \quad (1)$$

Figure 6 Lithium-7 NMR spectra of the molybdenum cluster chalcogenides (a) $\text{Li}_3\text{Mo}_6\text{S}_8$ and (b) $\text{Li}_3\text{Mo}_6\text{Se}_8$ obtained at 116.64 MHz and 100 K, and their simulations. (Reproduced by permission of the American Chemical Society from Prigge et al.⁵)

The powder spectrum is obtained from a weighted integration over the angles ϑ and φ in equation (1) which describe the orientation of the PAS of the nuclear quadrupole interaction (QF) tensor with respect to the laboratory frame (determined by $\mathbf{B}_0$). The Eulerian angles β and γ can be determined from the experimental spectra by simulation using equation (1). β is the angle between the z axes of the QF and CS tensors. The projection of the z axis of the QF tensor on the azimuthal plane of the PAS of the CS tensor with the x axis of the latter makes the angle γ . For $\beta = \gamma = 0$, equation (1) changes into the well known formula for the transition frequencies if the PASs coincide. The other symbols have their usual meanings. Instead of the (negative) shielding constant σ_{iso} , the isotropic chemical shift $\delta = 94$ (111) ppm relative to LiCl is given for $\text{Li}_3\text{Mo}_6\text{S}_8$ (in parentheses for $\text{Li}_3\text{Mo}_6\text{Se}_8$). The chemical shift anisotropy is $\Delta\sigma = -113$ (-90) ppm and the asymmetry factor $\eta_{\text{cs}} = 0$. The quadrupole data thus obtained from the spectra are $\chi = 75$ (95) kHz and $\eta_Q = 0.25$ (0.50). The angles turned out to be $\beta = 55^\circ$ and $\gamma = 90^\circ$ for both compounds. The DD interaction was taken into account by a Gaussian broadening with (full) width at halfheight of 8.2 (4.2) kHz. The results, and in

Figure 7 Dependence of the proton ^1H NMR spin-lattice relaxation rate upon reciprocal temperature for various hydrated chalcogenides $\text{A}_x(\text{H}_2\text{O})_y[\text{MS}_2]$ with $\text{A} = \text{Li}, \text{Na}, \text{K}, \text{Rb}, \text{or Cs}$, and $\text{M} = \text{Nb or Ta}$, measured at 15 MHz (dotted lines) and 30 MHz (solid lines). (Reproduced by permission of the American Institute of Physics from Röder et al.⁶)

particular the orientation of the PASs, can be well related to the structure, as will be shown in Section 4.

2.4 Molecular Motions

Molecular motions, the most important of which are those of the guest species, may either be studied from their influence on the spectra or by examining the relaxation behavior. An illustration of the first type of experiments was the example discussed in Section 2.2. If an intercalated molecule rotates, for instance, the Eulerian angles describing the orientation of the PAS (of the respective interaction) to $\mathbf{B}_0$ become time dependent and the spectra modified by partial averaging. In such cases it is useful to investigate the variation of the spectra with temperature.

Spin-lattice relaxation rates have been frequently used to explain details of the motional behavior. Two examples will be presented. Figure 7 shows $1/T_1$ versus reciprocal temperatures for hydrated transition metal disulfides with various alkali cations. The data depend strongly on the hydration enthalpy of the cations, and contain elements of low dimensionality. The fits were made on the basis of a model which included a logarithmic dependence on frequency, i.e. two-dimensional motions.⁶ The second example refers to a material which will be discussed in a later section.

The relaxation rates of ^7Li in $\text{Li}_3\text{Mo}_6\text{S}_8$ (Figure 8) can be explained by the superposition of a BPP term due to diffusion and a term which is proportional to the temperature. The latter arises from the interaction of the lithium nuclei with conduction electrons.

Slow motions have also been investigated in intercalation compounds using standard techniques. An example is the proton exchange rate, i.e. the mean lifetimes τ_e in hydrated transition metal disulfides obtained via creation of spin alignment by the 'Jeener-Broekaert' pulse sequence. τ_e values between about 1 and 100 ms were thus determined (Figure 9). They display an Arrhenius behavior which could be extrapolated to lower temperatures (and shorter lifetimes) by lineshape analysis.

3 STRUCTURE AND MOTIONS OF HYDRATED LAYERED CHALCOGENIDES

A class of intercalation compounds that was studied in some detail by NMR and where NMR contributed substantially to the understanding of the structure and dynamics comprises the hydrated transition metal chalcogenides of the alkali and alkaline earth elements with the formula $\text{A}_x(\text{H}_2\text{O})_y[\text{MX}_2]$, where $\text{M} = \text{Ti}, \text{V}, \text{Zr}, \text{Nb}, \text{Mo}, \text{Ta}, \text{or W}$ and $\text{X} = \text{S or Se}$. These

Figure 8 Lithium-7 NMR spin-lattice relaxation rate versus reciprocal temperature for the molybdenum cluster sulfide $\text{Li}_3\text{Mo}_6\text{S}_8$. The solid curve corresponds to the theoretical model description. (Reproduced by permission of the American Chemical Society from Prigge et al.⁵)

compounds can be regarded as polyelectrolytes consisting of two-dimensional $[\text{MX}_2]^{x-}$ macroanions (host lattice) with monolayers of mobile hydrated cations in the van der Waals gap between the sheets (guest species). We shall present here only an outline of the most important NMR experiments to investigate the structure and dynamics.

3.1 Proton NMR Spectra

The ^1H NMR spectra of the guest species (Figures 2 and 10) display the influence of intra- and intermolecular dipole-dipole couplings as well as CSA interactions. Separation is possible either by studying the magnetic field dependence or by application of a multiple pulse sequence (cf. Figure 10). In a sufficiently low magnetic field, at ambient temperature a nearly perfect Pake doublet of isolated H_2O can be observed, since the intermolecular interactions are averaged out by hopping motions of the water molecules. However, there is an additional central signal which increases at elevated temperatures and which was explained by proton exchange in these two-dimensional hydrated systems. The fast motion process was further investigated by NMR T_1 measurements (cf. Figure 7), and the slower proton exchange by spin alignment techniques (cf. Figure 9).

As a final result of several ^1H NMR studies including the examination of single crystals and oriented crystallites, all the water molecules in the van der Waals gap appear to be aligned with their C_2 axes lying in the a,b planes defined by the chalcogenide layers and their H-H vectors parallel to the c axis (Figure 11). The proton-proton separations amount to 165 pm; they are not significantly different from those in water of crystallization (158 pm). Two-dimensional diffusion and/or reorientation about the c direction leaves the orientation of the water molecules unchanged. The activation energy for this motion varies from 9 kJ mol^{-1} (Cs^+) to 50 kJ mol^{-1} (Li^+) depending on the central cation which interacts immediately with the negatively polarized dipole ends of the H_2O molecules.

Figure 9 Proton mean lifetime versus reciprocal temperature for water in the chalcogenides $\text{A}_x(\text{H}_2\text{O})_y[\text{NbS}_2]$ with $\text{A} = \text{Li}, \text{Na}, \text{K}, \text{Rb},$ or Cs derived from spin alignment measurements (solid symbols) and linewidth analysis (open symbols). (Reproduced by permission of VCH from E. Wein, W. Müller-Warmuth, and R. Schöllhorn, *Ber. Bunsenges. Phys. Chem.*, 1986, **90**, 158)

The diffusional motion of the water molecules explains also the axial symmetry of the chemical shift tensor derived from the spectra of Figure 10 (top). The PASs for the CS and DD interactions coincide. At lower temperature, the symmetry of the chemical shift disappears, and the intermolecular dipole interactions become important for broadening of the spectra (Figure 10) (bottom). The chemical shift anisotropy itself was found to depend greatly on the transition metal M . Going from W via $\text{Ta}(1 \text{ T})$, Mo , $\text{Ta}(2\text{H})$, Ti , Nb to V , $\Delta\sigma$ increases from -11 to $+69 \text{ ppm}$ for fully intercalated compounds ($x = 0.33$). Upon increasing the degree of reduction x between 0.08 and 0.33, $\Delta\sigma$ increases from 8 to 17 ppm for $M = \text{Ti}$; it decreases, however, from 60 to 33 ppm for $M = \text{Nb}$.

The large range of chemical shift anisotropies cannot be interpreted in terms of the electronic proton shielding within the guest phase. This should lead to a contribution of only about -10 ppm , a value which was observed as a limit in two of the compounds. In all other cases the significant positive contribution from the host lattice has to be taken into account in addition. The effect was found to depend on the particular conduction band of the dichalcogenide material and its filling with electrons. In NbS_2 the lowest-lying energy level is the d_{z^2} band, which is half occupied and becomes further filled up during the course of intercalation. The density of states at the Fermi level $D(E_F)$ has its maximum, therefore, in the absence of any intercalant, and decreases as a function of x , if guest species are intercalated and s electrons donated. $\Delta\sigma$ appears to be proportional to $D(E_F)$.

Figure 10 Proton NMR powder patterns of the hydrated layered compound $K_{0.25}(H_2O)_{0.75}[NbS_2]$ at two different temperatures (295 K, top and 150 K, bottom) measured in a magnetic field of 7 T. (a) Normal spectra. (b) Dipolar-decoupled spectra by MREV 8 multiple pulse sequences. The solid lines are computer simulations. (Reproduced by permission of VCH from M. Lobert, W. Müller-Warmuth, H. Katzke, and R. Schöllhorn, *Ber. Bunsenges. Phys. Chem.*, 1992, **96**, 1564)

This behavior was confirmed by the results for the compound $K_x(H_2O)_y[TiS_2]$. TiS_2 with the Group 4 element titanium has an empty d_{z^2} band, and, here, filling by progressive intercalation enhances both $D(E_F)$ and $\Delta\sigma$. Using the experimental data, the qualitative structure of the d_{z^2} band could be obtained for both compounds. The NMR results may be considered as a confirmation of the ‘rigid band model’, in which the only change to the electronic structure of the host is the increased d band filling. The proportionality between $\Delta\sigma$ and $D(E_F)$ was explained by the anisotropic Pauli paramagnetism; the magnetic susceptibility is also proportional to the density of states at the Fermi level.

3.2 Niobium-93 NMR Studies of the Intercalation

The process of intercalation from $x = 0$ to 0.33 could be studied in $K_x(H_2O)_y[NbS_2]$ and $K_x(H_2O)_y[NbSe_2]$ by observing the influence of the guest species on the ^{93}Nb NMR of the host lattice. The empty host lattices displayed spectra resembling those of Figures 3(a) and (b); the quadrupole coupling constants were determined with high accuracy, viz. 60.02 ± 0.02 MHz (60.05 ± 0.02 MHz) for $2H-NbS_2$ (and $2H-NbSe_2$). Intercalation of $K_x(H_2O)_y$ changes the mean local environment of niobium and reduces the coupling constant for a certain fraction of the ^{93}Nb NMR nuclei. For $x = 0.08$, 14% (11%) of the ^{93}Nb nuclei still have a coupling constant of 60 MHz, but 82% (89%) already one of 53 MHz, and 4% even one of 46 MHz. Upon increasing x further, the fractions with 60 MHz disappear in favor of the other two contributions. For $x = 0.33$ a coupling constant of 46 MHz (48 MHz) finally holds for 100% (41%) of the niobium sites in the NbS_2 ($NbSe_2$) host lattice. In $K_x(H_2O)_y[NbSe_2]$ the remaining 59% of ^{93}Nb nuclei experience the medium value of 53 MHz.

It is important to realize that there is no continuous variation of the NMR parameters with progressive intercalation, but there are three phases whose fractions change as a function of x . Structural variations are therefore responsible rather than electronic effects of the host. The three observed structures

were attributed to local staging. For $x = 0$, the relatively large quadrupole coupling belongs to niobium atoms, which all ‘see’ on one side of the two-dimensional arrangement the empty van der Waals gap. Upon increasing x , two new environments occur, one with intercalated species on both sides (local ranges of first-stage character), the other one with intercalated species on one side only (second-stage character). The smaller coupling constant of the final compound ($x = 0.33$) was attributed to a homogenous occupation of the van der Waals gap (‘first-stage compound’).

3.3 Further NMR Studies of Layered Compounds

Among the materials that were studied in some detail by NMR and which cannot be discussed within the scope of this short article are metal–ammonia compounds with certain similarities to hydrated systems. Intercalated atoms or ions in dichalcogenides, such as hydrogen, lithium and copper, were examined as well as intercalated molecules, e.g. ammonia, amines, derivatives of methane, pyridine, and even larger intercalants. Layered compounds also include graphite intercalation compounds, where, in particular, 1H , 7Li and ^{13}C NMR was applied on a large scale by various authors. Some layered oxides were investigated as well. Further details can be found in the literature.²

4 STRUCTURE AND DYNAMICS OF GUEST PHASES IN MOLYBDENUM CLUSTER CHALCOGENIDES

Binary and ternary molybdenum cluster chalcogenides (Chevrel phases) with the compositions Mo_6X_8 and $A_xMo_6X_8$ (A = main group metal; X = S or Se) have attracted considerable interest because of their unusual structure (Figure 11) and remarkable physical properties. Using NMR, compounds with intercalated lithium, sodium and copper were investigated. The behavior of lithium as the intercalant was examined in particular, with the result that four distinct phases with $x = 1, 3, 3.8$, and 4 could be identified from the different isotropic chemical shifts, as shown in Figure 12 (at room temperature, narrow singlet lines or first-order quadrupole spectra were observed). From the δ_{iso} values it was concluded that lithium appears to be ionic in $Li_1Mo_6X_8$ and $Li_4Mo_6X_8$ whereas lithium clusters with partial metallic character are formed in $Li_3Mo_6X_8$ and $Li_{3.8}Mo_6X_8$. More details were obtained from broadline spectra at low temperatures and from relaxation measurements.^{5,7}

In both $Li_1Mo_6X_8$ compounds the 7Li NMR spectra display in addition to DD and CA interactions ($\Delta\sigma = -11$ ppm at 100 K for $X = S$, and -15 ppm for $X = Se$) well resolved quadrupole structures of first order ($\chi = 107$ kHz and 79 kHz, respectively). The chemical shift tensor is axially symmetric ($\eta_{cs} = 0$), but the quadrupole asymmetry factor η_Q varies from 0.24 (0.10 for $X = Se$) at 100 K to zero at 300 K upon increasing the temperature. Spectra simulations led to the conclusion that the intercalated Li^+ ions reside in one of the six equivalent inner tetrahedral sites Li_1 of Figure 11(b) (bottom). Hopping motions between these positions are thermally activated; the correlation times are of the order of 10^{-7} – 10^{-3} s and follow an Arrhenius-type law (11 and 7 kJ mol $^{-1}$, respectively). In contrast to the other lithiated

Figure 11 Schematic representation of the structure of the compounds discussed in Sections 3 and 4. (a) Hydrated layered chalcogenides with the NbS₂ host lattice (top) and the arrangement of the H₂O molecules with the central cation (bottom). (b) Mo₆S₈ (• Mo, ○ S) structure with vacant channel positions (Δ) (top) and 2 × 6 potential lattice sites Li₁ (inner concentric ring) and Li₂ (outer ring) around the unit cell origin (bottom). The cavity is formed by sulfur atoms which belong to eight different Mo₆S₈ units

molybdenum cluster chalcogenides, at room temperature only this local motion is important; long range diffusion from cavity to cavity does not play a major role.

The extremely large δ_{iso} values of the Li₃Mo₆X₈ system were interpreted in terms of a Knight shift; the transfer of 2s electrons to the host lattice is incomplete, so that Li₃^{z+} clusters with $z < 3$ are formed. More detailed information was obtained from the ⁷Li NMR spectra at low temperatures, which are governed by DD, CS, and QF interactions. The chemical shift tensor appears to be axially symmetric, with $\Delta\sigma$ being relatively large and negative (−113 and −90 ppm for the compounds containing S or Se, respectively). This was interpreted in terms of a symmetric arrangement of three lithium atoms on the potential sites of Figure 11(b) (bottom). The z principal axis of the CS tensor may thus be identified with the symmetry axis perpendicular to the plane of the two concentric rings of possible lithium positions; the residual 2s electron density at the intercalated lithium provides stronger screening in the plane.

The principal axes of the CS and QF tensors do not coincide as shown in Figure 6 and equation (1). The PAS of the QF (EFG) tensor seems to agree with the rhombohedral reference system of the structure [Figure 11(b) (top)]. Then the angles β and γ describing the relative positions of the noncoincident PASs of the CS and QF tensors should become 54.54 and 90°, respectively, as observed experimentally. The quadrupole

coupling data are $\chi = 75$ kHz, $\eta_Q = 0.25$ (X = S), and $\chi = 95$ kHz, $\eta_Q = 0.50$ (Se).

The formation of lithium triclusters with short Li–Li distances and metal-like behavior is supported by spin–lattice relaxation measurements as in Figure 8. These contain in addition to a contribution from the lithium diffusion a term which is due to the interaction with conduction (2s) electrons and which fulfills the Korringa relation over a large range of temperatures. The diffusion of lithium species with activation energies of 13 and 19 kJ mol^{−1} corresponds to a high mobility of the translational motion from cavity to cavity. In contrast to Li₁Mo₆X₈, but in agreement with recent neutron diffraction studies,⁸ for Li₃Mo₆X₈ the inner ring of lithium sites is enlarged and provides, together with the outer ring, a framework of symmetrically arranged potential sites. The distances between these sites are short and comparable, and are well suited as a diffusion pathway. Application of the van Vleck formula for the DD interaction leads to an estimate of 210 pm (370 pm) for the Li–Li separation in the triclusters of Li₃Mo₆X₈ (Li₃Mo₆Se₈).

In contrast to stoichiometries with $3 < x < 3.8$ where two ⁷Li NMR signals appear, Li_{3.8}Mo₆S₈ is distinguished only by one NMR line, indicating a single-phase system. The chemical shift parameters ($\delta_{\text{iso}} = 39$ ppm, $\Delta\sigma = -45$ ppm)—though smaller than those of Li₃Mo₆S₈—and the other results, including relaxation, reveal that the lithium guest species possess metal-like properties as well. The Li–Li distances

Figure 12 Lithium-7 NMR isotropic chemical shift values (related to LiCl in aqueous solution) for $\text{Li}_x\text{Mo}_6\text{X}_8$ compounds (right). For the purpose of comparison, δ_{iso} values for various other lithium intercalation compounds and lithium metal are given (left)

are less and of the order of 330 pm, showing that the outer ring participates greatly in providing positions for the lithium atoms. The lithium mobility is again very high.

For the fully intercalated phases $\text{Li}_4\text{Mo}_6\text{X}_8$ there is no longer any Knight shift, and the chemical shift anisotropy is very small as well. Only the quadrupolar and dipolar data are of comparable orders of magnitude, but here the EFG values are somewhat distributed. The lithium mobility is much less as compared with the Li_3 and $\text{Li}_{3.8}$ compounds. The dramatic transition from Li_3 to Li_4 , as observed by NMR and manifested by the macroscopic properties of the material, can

be related to the electronic structure and to the arrangement of potential lithium sites. The inner ring is no longer enlarged, and there is a large separation between the Li1 and Li2 positions comparable to that in $\text{Li}_1\text{Mo}_6\text{X}_8$.

1 INTRODUCTION

1.1 General Aspects

The element lithium (from the Greek *lithos* = stone), discovered in 1817 by Arfvedson in the Swedish mineral *petalit*, has two stable isotopes, lithium-6 (${}^6\text{Li}$) and lithium-7 (${}^7\text{Li}$) in 7.42 and 92.58% natural abundance, respectively, which are both NMR active. Their position within the group of quadrupolar metal nuclei with respect to natural abundance and receptivity for the NMR experiment is shown in Table 1.

Historically it is of interest that an early, albeit unsuccessful, attempt to detect NMR in bulk matter was performed with powdered lithium chloride.³ Only later did it become clear that under the experimental conditions used the ${}^7\text{Li}$ resonance was probably saturated. The first ${}^7\text{Li}$ NMR signal was recorded in 1946,⁴ while ${}^6\text{Li}$ was measured a few years later.⁵ High-resolution spectra for ${}^7\text{Li}$ were then reported in 1962⁶ and for ${}^6\text{Li}$ in 1976.⁷ For completeness, we mention that nuclear properties of the short-lived nuclides ${}^8\text{Li}$ ($I = 2$, half-life 0.88 s)⁸ and ${}^9\text{Li}$ ($I = \frac{3}{2}$, half-life 178 ms)⁹ have been studied in order to test nuclear models. Another unstable lithium nuclide is ${}^{11}\text{Li}$ (half-life 8.7 ms), with a spin of $I = \frac{3}{2}$. In the following discussion we use the notation ${}^{6,7}\text{Li}$ when discussing aspects relevant to both nuclei, and ${}^6\text{Li}$ or ${}^7\text{Li}$ otherwise. As in similar cases where different nuclides of the same element are reviewed, the chemical shifts (in ppm) are identical, scalar spin–spin coupling constants are related by the factor $\gamma({}^7\text{Li})/\gamma({}^6\text{Li})$, and relaxation mechanisms differ.

The properties of the stable lithium nuclides which are important for the NMR experiment are collected in Table 2, where data for the widely used nuclei ${}^1\text{H}$ and ${}^{13}\text{C}$ are included for comparison. Both ${}^6\text{Li}$ and ${}^7\text{Li}$ possess a quadrupole moment Q , but that of ${}^6\text{Li}$ is the smallest known for any nucleus. NMR of ${}^6\text{Li}$ is, therefore, not dominated by its quadrupole moment, and ${}^6\text{Li}$ has been termed an ‘honorary spin- $\frac{1}{2}$ nucleus’.¹⁰ The most pronounced advantage of ${}^6\text{Li}$ over ${}^7\text{Li}$ is the smaller NMR linewidth attainable in high-resolution measurements of liquids. The halfwidth $w_{1/2}$ of an NMR signal from a quadrupolar nucleus depends on molecular motion, characterized by the correlation time τ_c , its spin quantum number I , its electric quadrupole moment Q , the electric field gradient at the nucleus q_{zz} , and η , the asymmetry parameter of q , according to¹³

$$w_{1/2} = \frac{3}{10}\pi Q^2 \cdot \frac{(2I+3)}{I^2(2I-1)} \cdot \frac{e^4}{h^2} q_{zz}^2 (1 + \frac{1}{3}\eta^2) \tau_c \quad (1)$$

For the linewidth factor WF of a certain nuclide we then have, for constant electric field gradients,

$$\text{WF} = Q^2 \frac{(2I+3)}{I^2(2I-1)} \quad (2)$$

and with the data for the various parameters given in Table 2 we find that the smaller quadrupole moment of ${}^6\text{Li}$ renders WF(${}^6\text{Li}$) smaller than WF(${}^7\text{Li}$) by three orders of magnitude. Similarly, in solid state MAS experiments, ${}^6\text{Li}$ produces fewer sidebands than the heavier nuclide ${}^7\text{Li}$.¹⁴ In general, however, both ${}^6\text{Li}$ and ${}^7\text{Li}$ are less subject to quadrupolar effects than the heavier alkali metal nuclei because the Sternheimer antishielding factor, which is a measure of the effective field gradient produced at a nucleus as a result of the polarization effect induced for the atomic electron cloud by an external field gradient, is one to two orders of magnitude smaller for lithium than for the other alkaline metals (Table 2).

${}^6\text{Li}$ and ${}^7\text{Li}$ NMR spectra of liquids are conveniently measured with broadband probeheads in the FT mode employing the standard deuterium lock system. For organolithium compounds, spectra are usually run with ${}^1\text{H}$ decoupling in order to remove line broadening due to ${}^{6,7}\text{Li}$ – ${}^1\text{H}$ spin–spin coupling (see Section 2.4). In addition, a considerable intensity increase may result for ${}^6\text{Li}$ measurements due to $\{^1\text{H}\}^6\text{Li}$ NOEs (see Sections 2.6 and 3.2.1). Therefore, many NMR spectroscopists nowadays prefer to measure ${}^6\text{Li}$ instead of ${}^7\text{Li}$, despite its lower receptivity. In order to eliminate the disadvantage of lower natural abundance, isotopic ${}^6\text{Li}$ labeling is widely used and lithium-6 metal is commercially available for this purpose. Due to ${}^6\text{Li}$ depletion of lithium metal in connection with its use in the atomic energy industry, the isotopic composition of lithium in commercially available compounds may vary. If necessary, the lithium isotopic abundance of a sample can be conveniently determined by comparing the NMR signal intensities of an unknown sample with that of a sample with known isotopic composition.

Long relaxation times (see Section 2.1) may sometimes cause difficulties for ${}^6\text{Li}$ NMR measurements. This has to be taken into account by choosing a sufficiently long relaxation delay between individual transients if data accumulation is used. It is of interest to note that the ${}^2\text{H}$ NMR frequency is close to that of ${}^6\text{Li}$ [61.40 versus 58.87 MHz on a 400 MHz (${}^1\text{H}$) instrument]. For many probeheads, the ${}^2\text{H}$ coil can thus be tuned to the ${}^6\text{Li}$ frequency if this is desirable for certain experiments, for example ${}^6\text{Li}$ decoupling during ${}^{13}\text{C}$ observation. Determination of the 90° pulse is usually performed by standard techniques (180° , 360° search) with an aqueous or tetrahydrofuran solution of a lithium salt. If long relaxation times are anticipated, steady state pulse calibration¹⁵ can be used to advantage. Selective excitation of ${}^6\text{Li}$ signals has been achieved using the DANTE sequence¹⁶ in the case of overlapping ${}^6\text{Li}$ multiplets which resulted from ${}^6\text{Li}$, ${}^{13}\text{C}$ coupling in a ${}^{13}\text{C}$ labeled organolithium compound.¹⁷

An important aspect of ${}^{6,7}\text{Li}$ NMR measurements is the dynamic behavior of the systems which contain the ${}^{6,7}\text{Li}$ nuclei to be studied. In salt solutions and in solutions of organometallic compounds, exchange processes operate and

the spectral properties measured may be average values for various species. This is certainly true for room temperature measurements of most organolithium compounds and must be kept in mind when ^{6,7}Li NMR parameters are discussed. It is only in the slow exchange limit, usually well below -50°C , where ^{6,7}Li resonances of individual aggregates such as monomers, dimers, or tetramers (Figure 1) can be detected. If only one particular specimen is present, exchange does not affect spin–lattice relaxation times and chemical shifts, but it averages or completely eliminates line splittings due to scalar spin–spin coupling to neighboring nuclei.

1.2 Applications of ^{6,7}Li NMR

High-resolution ^{6,7}Li NMR measurements are applied primarily in two different areas: measurements on ionic lithium in aqueous or nonaqueous solutions, on the one hand, and on lithium covalently bound mainly to carbon, nitrogen, or phosphorus in organometallic compounds on the other. The first encompasses research in inorganic chemistry and on the structure and dynamics of ion solvation. The second area is largely a domain of structural research in organometallic chemistry. In addition, due to the physiological effects of lithium ions, ^{6,7}Li NMR also extends to biochemistry as well as physiological and medical chemistry, an area not covered in this article.

1.3 Literature Review

There are a number of extensive reviews on alkaline metal NMR where data for ⁶Li and ⁷Li are reported. The earlier articles by Lindman and Forsén (1978),¹⁸ Wehrli (1979),¹⁹ Laszlo (1983),¹⁰ Detellier (1983),²⁰ and Akitt (1987)²¹ concentrate on NMR studies of ions in aqueous and nonaqueous solutions. Work on simple electrolyte solutions was treated by Holz (1986).²² NMR of metal nuclei in organometallic compounds in general has been reviewed by Dechter (1982)¹ and Benn and Rufinska (1985)² and NMR of organolithium compounds is the subject of the more recent articles by Günther et al. (1987),²³ Thomas (1991),²⁴ Jackman,²⁵ Bauer and Schleyer (1992),²⁶ Collum (1993),²⁷ and Bauer (1994, 1995).²⁸ The pioneering work in this field has been summarized by Brown,²⁹ 30 McKeever,³¹ and Fraenkel.³²

2 THE NMR PARAMETERS OF ${}^6,{}^7\text{Li}$

2.1 Longitudinal Relaxation

2.1.1 Electrolyte Solutions

Longitudinal relaxation measurements for ${}^6,{}^7\text{Li}$ have been performed on the ions in aqueous and nonaqueous solutions as well as in mixed solvents and on organolithium compounds in organic solvents. Aside from an inherent interest in the relaxation mechanisms, such studies were undertaken in order to investigate solvation and coordination effects, ion–ion and ion–solvent interactions, ion and molecular dynamics as well as molecular structure.

For aqueous solutions of inorganic salts, the relaxation of the free ions is characterized by quite small longitudinal relaxation rates R_1 . As compared with the familiar spin- $\frac{1}{2}$ nuclei, an interesting aspect of ${}^6,{}^7\text{Li}$ relaxation is the role played by the quadrupolar mechanism. As it turns out, both ${}^6\text{Li}^+$ and ${}^7\text{Li}^+$ have been found to be relaxed by dipolar mechanisms in aqueous solution involving hydrate protons, while quadrupolar relaxation dominates for the heavier alkaline metals. Studies of several lithium salts have shown that the longitudinal relaxation of ${}^7\text{Li}^+$ is governed by a mixture of dipolar and quadrupolar contributions of comparable weight. For lithium halides in H_2O at 25°C , R_1 ranges between 0.05 and 0.5 s^{-1} , depending on concentration, with dipole–dipole contributions of about 0.03 s^{-1} .³³ Due to its relatively long relaxation times, ${}^7\text{Li}$ is also of interest for measurements of ion velocities in connection with direct current or electrophoretic NMR.³⁴

A mechanistic study on ${}^6\text{Li}^+$ in aqueous lithium chloride⁷ showed that 84% of the relaxation is dipolar, 8% is spin rotation, while quadrupolar relaxation accounts for less than 0.1% and is thus negligible. The separation of the dipolar portion was accomplished on the basis of NOE experiments (see Section 2.6). Since the measurements were performed with lithium of natural isotopic distribution, a possible contribution of ${}^7\text{Li}$ – ${}^6\text{Li}$ dipole interaction was also evaluated, but was found to be insignificant; 7% of the experimental relaxation rate has not been assigned and has been attributed to the presence of a small concentration of paramagnetic impurities. While in H_2O the relaxation rate (at 30°C) is as small as 0.0059 s^{-1} , it is even smaller in D_2O (0.0012 s^{-1}). At 80°C , T_1 was found to be $1040 \pm 50\text{ s}$ which is probably the longest T_1 observed so far in the liquid phase. Because of the smaller magnetic moment of the deuteron the ${}^6\text{Li}$ – ${}^2\text{H}$ dipolar interaction is only about 7.5% of that in H_2O .

Several models have been developed for the mechanism of ion quadrupolar relaxation which are, according to the facts discussed above, more important for the heavier alkaline ions than for ${}^6,{}^7\text{Li}$, and will therefore be mentioned only briefly. The *electrostatic model* has been worked out by Valiev³⁵ and Hertz.³⁶ A detailed treatment distinguishes between three states of solvation: (1) a fully random distribution (FRD) model assumes both a random distribution and random orientation of the solvent molecules; (2) a model with nonoriented solvation, i.e. with a distinct first solvation sphere, but with random orientation of the solvent dipoles; and (3) a fully oriented solvation (FOS) model which is characterized by a distinct first solvation sphere with radial orientation of the solvent dipoles. In each case, relaxation is

caused by the electric field gradients arising from the dipole moments of the solvent molecules, which are modulated by rotational and translational motion. The *electronic distortion model*, developed by Deverell,³⁷ assumes on the other hand that distortions of the spherical symmetry of the electron cloud are the origin of the field gradients causing relaxation. Such a mechanism also affects the paramagnetic term of the shielding constant. While the electrostatic model has found widespread application, the complexity of the physical problem involved has initiated further investigations³⁸ and studies on quadrupolar relaxation in general continue.³⁹

2.1.2 Organometallic Compounds

${}^7\text{Li}$ and ${}^6\text{Li}$ spin–lattice relaxation times have been determined for organolithium compounds in solution.^{40,24} The T_1 values vary from 0.01 to 10 s, and it was concluded that for ${}^7\text{Li}$ the quadrupolar relaxation mechanism dominates. Recent findings of $\{^1\text{H}\}^7\text{Li}$ NOE effects, however, show that in symmetric surroundings considerable dipolar contributions to ${}^7\text{Li}$ relaxation can exist.^{41,42} ${}^6\text{Li}$ T_1 values in organolithium compounds are typically of the order of seconds or even tens of seconds. Measurements for methyl-, *n*-butyl-, and phenyllithium in diethyl ether and hydrocarbon solvents⁴³ yielded T_1 values of 9 to 72 s, while the ${}^7\text{Li}$ T_1 values for the same compounds determined from identical samples are one to two orders of magnitude smaller. As again evidenced by the NOE effect, the ${}^6\text{Li}$ – ${}^1\text{H}$ dipolar contribution to the overall relaxation rate was found to be 20, 35, and 17%, respectively. Assuming that ${}^7\text{Li}$ relaxes entirely by the quadrupolar mechanism, quadrupolar contributions of 5, 24, and 27%, respectively, can be calculated for ${}^6\text{Li}$ relaxation in the three species.⁴⁴ A possible ${}^7\text{Li}$ – ${}^6\text{Li}$ dipolar contribution was estimated to be 6%. A much larger contribution (30–60%) from this source was found by Thomas,²⁴ who compared T_1 data from ${}^6\text{Li}$ enriched organolithium compounds with those from compounds with natural ${}^6,{}^7\text{Li}$ distribution. A strong solvent effect on these parameters was also noted, while variable temperature studies showed a decrease in T_1 with decreasing temperature, as expected.²⁴

The different contributions of ${}^6\text{Li}$ and ${}^7\text{Li}$ to the spin–lattice relaxation of neighboring nuclei provide, in suitable cases, a means for the determination of Li–C and Li–H distances in aggregates of solute organolithium compounds through the use of the isotopic substitution method,⁴⁵ as has been shown for phenyllithium by Jackman.⁴⁶ If one replaces a nucleus ${}^n\text{X}$ (spin quantum number I) with strong dipole–dipole interaction by its isotope ${}^m\text{X}$ (spin quantum number S) with weak dipole–dipole interaction, the difference in the spin–lattice relaxation rate R_1 of the neighboring ${}^{13}\text{C}$ nucleus is given by

$$R_1^{\text{exp}}({}^n\text{X}) - R_1^{\text{exp}}({}^m\text{X}) = R_1^{\text{DD}}({}^n\text{X}) \left[1 - \frac{\gamma_{m_x}^2 S(S+1)}{\gamma_{n_x}^2 I(I+1)} \right] \quad (3)$$

If the correlation time τ_c is known, the distance $r_{\text{C-X}}$ can be determined according to

$$r_{\text{C-X}} = \sqrt[6]{\hbar^2 \gamma_{13\text{C}}^2 \gamma_{n_x}^2 \tau_c / R_1^{\text{DD}}({}^n\text{X})} \quad (4)$$

τ_c is obtained from the dipolar relaxation rate R_1^{DD} of another ${}^{13}\text{C}$ nucleus in the same molecule, measured under identical conditions, and its respective C–H distance.

Finally, we mention that ${}^7\text{Li}$ $T_{1\rho}$ measurements have been used to study the rate of interconversion between tight and loose ion pairs of lithium fluorene.⁴⁷ The quadrupolar relaxation contribution was derived from ${}^6\text{Li}$ and ${}^7\text{Li}$ T_1 data, and a change in the ${}^7\text{Li}$ quadrupole splitting constant (QSC), obtained via ${}^7\text{Li}$ quadrupolar and ${}^{13}\text{C}$ dipolar relaxation rates, with ion pair structure was indicated.

2.2 Transverse Relaxation

For quadrupolar nuclei with dominant quadrupolar relaxation, the relaxation rates for longitudinal and transverse magnetization (R_{1q} and R_{2q}) are identical in the motional narrowing limit. This situation is met in many cases for ${}^7\text{Li}$, while for ${}^6\text{Li}$ the relation $R_2 > R_1$ will generally be found. For both nuclei, however, chemical exchange processes are quite common and the strongest contribution to R_2 will then originate from this source. This topic is discussed in Section 3.2.2.

2.3 Chemical Shifts

2.3.1 Reference Methods

Since chemical shifts are measured relative to the signal of a reference compound, the problem of referencing is an experimental detail of practical importance. For ${}^{6,7}\text{Li}$ measurements internal standards are not feasible in either inorganic or organometallic applications due to exchange reactions involving Li^+ . Furthermore, in the study of organometallic compounds the high sensitivity of these systems towards acids as well as their general reactivity prevent the use of internal references. ${}^{6,7}\text{Li}$ chemical shifts have, therefore, been recorded relative to various external standards, as for example 1.0 or 0.1 molar solutions of lithium salts (LiCl , LiBr , or LiClO_4) in H_2O or organic solvents like tetrahydrofuran (THF) and the data are generally reported without bulk susceptibility corrections. As Thomas has pointed out,²⁴ due to the different correction terms this may lead to chemical shift differences of several tenths of a ppm if data from iron magnets are compared with data from superconducting magnets.

An alternative method for referencing ${}^{6,7}\text{Li}$ shifts in organolithium compounds has recently been proposed by Jackman.⁴⁸ This method takes advantage of the multiple frequency probes and rf systems of modern spectrometers and is independent of volume susceptibility differences and the nature of the lock substance. The spectrometer has to be calibrated with, for example, a 0.3 M solution of LiCl in methanol- d containing 5% TMS. The methanol ${}^{13}\text{C}$ signal (secondary ${}^{13}\text{C}$ reference) is then referenced to the primary ${}^{13}\text{C}$ standard [tetramethylsilane (TMS)] which yields

$$\nu_{\text{ref}}({}^{13}\text{C}) = \nu_{\text{tr}}({}^{13}\text{C}) + \Delta\nu_{\text{off}}({}^{13}\text{C}) - \Delta\nu_{\text{shift}} \quad (5)$$

where ν_{tr} is the transmitter frequency, $\Delta\nu_{\text{off}}$ the offset between the secondary standard and the transmitter, and $\Delta\nu_{\text{shift}}$ is the methanol–TMS frequency difference (all quantities in hertz).

In the next step, $\nu_{\text{ref}}({}^{6,7}\text{Li}) = \nu_{\text{tr}}({}^{6,7}\text{Li}) - \Delta\nu_{\text{off}}({}^{6,7}\text{Li})$ is determined for the standard sample. A ${}^{13}\text{C}$ resonance of the sample of interest is then measured to yield $\nu_{\text{ref}}'({}^{13}\text{C}) - \nu_{\text{ref}}({}^{13}\text{C})$ and a new absolute ${}^{6,7}\text{Li}$ reference frequency $\nu_{\text{ref}}'({}^{6,7}\text{Li})$ is obtained from the relationship

$$\frac{\nu_{\text{ref}}'({}^{6,7}\text{Li}) - \nu_{\text{ref}}({}^{6,7}\text{Li})}{\nu_{\text{ref}}'({}^{13}\text{C}) - \nu_{\text{ref}}({}^{13}\text{C})} = \frac{\gamma({}^{6,7}\text{Li})}{\gamma({}^{13}\text{C})} \quad (6)$$

or

$$\nu_{\text{ref}}'({}^{6,7}\text{Li}) = \nu_{\text{ref}}({}^{6,7}\text{Li}) + [\nu_{\text{ref}}'({}^{13}\text{C}) - \nu_{\text{ref}}({}^{13}\text{C})]\gamma({}^{6,7}\text{Li})/\gamma({}^{13}\text{C}) \quad (7)$$

The difference $\nu_{\text{ref}}'({}^{6,7}\text{Li}) - \nu_{\text{tr}}({}^{6,7}\text{Li})$ gives the offset (in hertz) required to reference the unknown lithium sample.

2.3.2 Structural Effects

As compared with other metal nuclei, the ${}^{6,7}\text{Li}$ chemical shift scale is rather small and the NMR signals of ${}^{6,7}\text{Li}$ encompass not more than about 6 ppm for salt solutions and about 12 ppm for organolithium compounds. This can be attributed to the relatively small paramagnetic contribution to the shielding constant of ${}^{6,7}\text{Li}$, which leads to a near-cancellation of the diamagnetic term.⁴⁹ Due to the larger gyromagnetic ratio, spectral dispersion is better for ${}^7\text{Li}$ than for ${}^6\text{Li}$, but the larger ${}^7\text{Li}$ linewidth (see above) may jeopardize this advantage. In addition, ${}^{6,7}\text{Li}$ shifts are sensitive to solvent effects, viscosity, temperature and concentration and these effects are of the same order as the structural effects. For solvent effects alone, a range of nearly 6 ppm was found for $\delta({}^7\text{Li})$ (Table 3).^{50,51} Therefore, a comparison of $\delta({}^{6,7}\text{Li})$ values is difficult and, because of these uncertainties, ${}^{6,7}\text{Li}$ chemical shift arguments have been used in structural research to a much lesser extent than in the case of other nuclei. Furthermore, in the absence of spin–spin coupling, an unequivocal assignment of ${}^{6,7}\text{Li}$ resonances is not always possible.

The chemical shift of lithium ions has been investigated in connection with studies on ion pairing, solvation, and complexation, where sudden shifts are typically observed upon formation of complexes with defined stoichiometry. In the solvent effect studies, no correlation of $\delta({}^7\text{Li})$ with solvent properties was found, contrary to the situation with other alkaline metal ions and the influence of counterions on $\delta({}^7\text{Li})$ is solvent dependent.⁵¹ These studies, which include ${}^7\text{Li}$ measurements of the complexation of crown ethers and cryptands, as well as naturally occurring ionophores, have been reviewed by Wehrli,¹⁹ Dechter,¹ Detellier,²⁰ and most recently by Bartsch et al.¹⁶⁶ A graphical overview on ${}^7\text{Li}$ chemical shifts, presented by Akitt,²¹ is given in Figure 2.

The ${}^{6,7}\text{Li}$ resonances of organolithium compounds were measured in different solvents, and representative results are shown in Figure 3⁵² and Table 3. Some of the observed trends can be correlated with the structure of the ligands or the chemical bonding situation. There is a remarkable shielding effect, generally classified as a *ring current effect* on the ${}^{6,7}\text{Li}$ resonance in polyhaptol lithium compounds of organic π systems,^{53–56} where lithium is situated above the plane of the π system (Table 4). Low-frequency and high-frequency shifts indicate diatropic and paratropic properties, respectively. The shielding effect is most pronounced for situations where Li^+ is sandwiched between two π systems,^{55,57–59} but smaller than expected in dianions of condensed benzenoid aromatics. Similarly, the study of ${}^7\text{Li}$ chemical shifts for a variety of alkyllithium compounds⁵² (Figure 3) revealed that

$\delta({}^7\text{Li})$ is strongly influenced by the diamagnetic anisotropy of the organic ligands. A distinct low-frequency shift was observed in the majority of cases by changing the solvent from hydrocarbons to diethyl ether. For aryllithium compounds systematic substituent effects were found with

high-frequency shifts for donor substituents in positions *meta* and *para* to the metallated carbon.⁶⁰ Low-temperature studies, which allow the measurements of ${}^6,{}^7\text{Li}$ shifts for different aggregates of a particular system, showed that in a number of cases ${}^6,{}^7\text{Li}$ is less shielded in the higher aggregates

Figure 2 Graphical summary of $^{6,7}\text{Li}$ chemical shifts in (a) salt solutions, and (b) organolithium compounds. (Reproduced by permission of Plenum Press from J. W. Akitt, in 'Multinuclear NMR', ed. Joan Mason, New York, 1987, Chap. 7)

(Table 3).^{61,62} This cannot be regarded as a general rule, however, because the reverse order has also been observed.^{63,64} For mixed aggregates between simple alkyl lithium compounds and lithium salts, a type of *heavy atom effect* is documented by the shielding observed with increasing incorporation of halide ions (Table 3).^{61,65} $^{6,7}\text{Li}$ chemical shifts (in particular the shielding effects of π systems) have been used as probes for ion pairing.^{66–68} *IGLO calculations*⁶⁹ reproduce the effect of π systems well. In general, rather little variation of the shielding constant σ with chemical structure was found, in agreement with experimental observations (see above). Nevertheless, the results of such calculations for $^{6,7}\text{Li}$ chemical shifts have been shown to provide important insights into the structure–chemical shift relationship.⁵⁷

2.3.3 Deuterium-Induced Isotope Effects on ^6Li Chemical Shifts

Theoretical calculations on LiH and LiD predicted a deuterium-induced high-frequency (downfield) ^6Li shift,⁷⁰ but early measurements on $^{6,7}\text{Li}$ salt solution in deuterated and nondeuterated solvents failed to demonstrate isotope shifts.⁷¹ The first observation of deuterium-induced shifts for the ^6Li resonance was reported for deuterated methyllithium, where an isotope shift $\Delta\delta$ of 16 ppb was found.⁶⁵ Based on this

observation, the *isotopic fingerprint method* was developed as a tool for structural investigations in the field of organolithium compounds.⁶⁵ With this method, typical ^6Li multiplets, which are characteristic of the aggregation state, can be expected for 1:1 mixtures of deuterated and nondeuterated RLi compounds in the region of slow inter- and intra-aggregate exchange. The principle of this technique, which is closely related to the SIMPLE NMR method for the assignment of ^{13}C NMR spectra of polyalcohols,^{72,73} is best explained by using an example.

Given a dimeric structure of type (1), like that of phenyllithium ($\text{R} = \text{C}_6\text{H}_5$) in the presence of tetramethylethylenediamine (TMEDA),⁷⁴ and a 1:1 mixture of deuterated and nondeuterated ligands R (d and h, respectively), the ^6Li environments (2)–(4) exist.

According to a straightforward statistical consideration, a ^6Li triplet with an intensity distribution of 1:2:1 should then result in the case of slow inter-aggregate exchange, if a $^2\text{H}/^1\text{H}$ isotope effect for $\delta(^6\text{Li})$ exists. Each line of this multiplet is characteristic for a different ^6Li environment. In turn, for a monomer we should find a doublet and for a tetramer with three direct neighbors (see Figure 1), a quadruplet with an intensity distribution of 1:3:3:1 is expected. Thus, clusters of different size are characterized by isotopic fingerprints, where the intensity ratio follows Pascal's triangle (Figure 4). An attractive feature of this method as compared to the

determination of the aggregation number from scalar ^{13}C – ^6Li or ^{13}C – ^7Li spin–spin coupling constants (see later) is its sensitivity which is achieved by twofold isotopic enrichment (^2H and ^6Li).

If only the inter-aggregate exchange is slow and the intra-aggregate exchange is still fast on the NMR timescale, the situation changes for clusters with aggregation numbers >2 . The ^6Li nucleus then interacts with all ligands of the particular clusters, including the remote ones. Consequently, for a dynamic tetramer a 1:4:6:4:1 ^6Li quintuplet is then expected. Now, each line of the multiplet corresponds to a different aggregate (Figure 4). The isotopic fingerprint method has been applied to study the aggregation of alkyl- and aryllithium compounds,^{61,65,75} of lithium diisopropylamide⁷⁵ and of mixed aggregates between methylolithium and LiI ⁶⁵ as well as LiBr .⁶¹ These studies also revealed the existence of isotope shifts transmitted over more than two bonds. In all cases high-frequency shifts for the ^6Li resonance were observed.

2.4 Scalar Spin–Spin Coupling

2.4.1 General Aspects

Homo- and heteronuclear scalar spin–spin coupling of $^{6,7}\text{Li}$ is a domain of organolithium compounds. It is of great importance for structural investigations and yields information about chemical bonding between lithium and other elements like carbon, nitrogen, or phosphorus. In particular, coupling between ^6Li and ^{13}C has led to a wealth of structural information on organolithium aggregates in solution. Due to the higher gyromagnetic ratio of ^7Li , ^7Li –X coupling constants are larger by a factor of $\gamma(^7\text{Li})/\gamma(^6\text{Li}) = 2.64$ than ^6Li –X coupling constants. As in the case of chemical shifts,

this advantage is, however, very often annihilated by ^7Li quadrupolar effects, which lead to line broadening and partial decoupling. This is demonstrated by the ^{13}C NMR signal shown in Figure 5.

An important aspect with respect to the experimental observation of spin–spin coupling is the fact that lithiated carbon, nitrogen, silicon, and phosphorus compounds exist in the solid as well as in solution as aggregates or clusters (see Figure 1). Extensive X-ray work has revealed a large variety of solid state structures⁷⁶ which are, primarily according to the results of NMR investigations, also retained if the compounds are dissolved in hydrocarbon or ethereal solvents. However, in solution different, coexisting aggregates are formed in many cases and these systems become dynamic. Thus, intra- as well as inter-aggregate exchange operates and the observation of line splittings due to scalar coupling therefore crucially depends on the NMR timescale. Only in the slow exchange limit can couplings be detected, and thus measurements have to be performed almost exclusively at low temperatures ($T < -50^\circ\text{C}$). Starting in the high-temperature, fast exchange regime, one gradually slows down the inter- and the intra-aggregate exchange by low-temperature measurements until exchange is slow enough for individual species to be observed. Only rarely can these different stages be ‘frozen out’ stepwise,^{77–79} and in general two situations are met. (1) If the energy barriers of the two fluxional processes are very similar, low-temperature measurements may lead directly to *static aggregates* where spin–spin coupling to $^{6,7}\text{Li}$ originates in the case of the heavier nuclei from nearest neighbors (‘local environment approximation’⁸⁰). (2) The barrier to intra-aggregate exchange may be low and only the inter-aggregate exchange can be slowed down. In these fluxional aggregates the observed line splittings result from an average of the spin–spin interactions between $^{6,7}\text{Li}$ and directly bonded and remote X nuclei. Since coupling to remote nuclei is smaller than the coupling to the direct neighbors or may even be zero, smaller line splittings are observed in these cases as compared with the situation met with static

Figure 3 ^7Li chemical shifts for alkyl and alkenyl lithium compounds in different solvents relative to 0.1M LiBr as external reference. (Reproduced with permission from P. A. Scherr, R. J. Hogan, and J. P. Oliver, *J. Am. Chem. Soc.*, 1974, **96**, 6055)

aggregates, but the multiplicity of the observed resonances is higher than in the static case.

2.4.2 Homonuclear Coupling

Homonuclear spin-spin coupling between nonequivalent lithium atoms in organolithium compounds is weak ($J <$

0.5 Hz). It was first detected indirectly by cross peaks in homonuclear ^6Li - ^6Li COSY spectra.⁸¹ Only recently, such a coupling (magnitude 0.16 Hz) could be resolved for the dimer of (*E*)-2-lithio-1-phenyl-1-(*o*-lithiophenyl)pent-1-ene⁸² (for the structure of this compound see Figure 10). The coupling is best detected by the INADEQUATE experiment,⁸³ where the resulting antiphase magnetization facilitates the observation of line splittings which are otherwise barely resolved (see later). Indirect detection of ^7Li - ^7Li couplings was recently achieved by means of ^7Li - ^7Li COSY and ^7Li - ^7Li INADEQUATE experiments.⁸⁴

2.4.3 Heteronuclear Coupling

2.4.3.1 General Aspects. Due to the more favorable NMR properties and the possibility of 100% isotopic enrichment, scalar couplings to lithium are measured more easily in the majority of cases for ^6Li . Only where the larger magnitude of ^7Li couplings promises an advantage is the use of ^7Li preferable. For $^6\text{Li}_n\text{-X}_m$ spin pairs, scalar coupling can be observed in the ^6Li as well as in the X spectrum if high natural abundance exists (^6Li enrichment, $X = ^1\text{H}$ or ^{31}P). In case of X nuclei with low natural abundance (^{13}C or ^{29}Si), coupling is best measured in the X spectrum, since in the $^{6,7}\text{Li}$ spectra only X satellites are observed (Figure 6).^{78,85} For the detection of ^{15}N - ^6Li coupling, ^{15}N enrichment is required because of the low natural abundance of ^{15}N (0.37%) and the low substrate concentrations usually attainable as a consequence of low solubility.

If $^{6,7}\text{Li-X}$ couplings are well resolved, as is the case for $X = ^{13}\text{C}$, ^{15}N , or ^{31}P , spin multiplets are observed which are determined by the relevant spin quantum numbers. For first-order spectra, the multiplicity M of the resonances then follow the well-known rules with $M = 2nI + 1$, where n is the number of adjacent nuclei. For the $^{6,7}\text{Li}$ resonances of lithium coupled to spin- $\frac{1}{2}$ nuclei, $M = n + 1$; while for X nuclei coupled to ^6Li , $M = 2n + 1$; and for those coupled to ^7Li , $M = 3n + 1$. The intensity distribution of the $^{6,7}\text{Li}$ resonances is given by the binomial coefficients, and those of the X resonances are summarized in Figure 7. In recent years, investigations of polylithium compounds have revealed spin systems that are more complicated than first order (see below).

2.4.3.2 $^{6,7}\text{Li-H}$ Coupling. Scalar spin-spin coupling between protons and $^{6,7}\text{Li}$ is again rather small (<1 Hz), except in hydrido complexes where large $^7\text{Li-H}$ interactions have been reported in two cases [(**5**), $J = 8.4$ Hz;⁸⁶ (**6**) $J = 10.5$ Hz⁸⁷]. In organolithium compounds $^{6,7}\text{Li-H}$ coupling has been recognized from ^1H lineshape changes observed by comparing ^7Li and ^6Li labeled compounds⁸⁸ and by lineshape simulations of ^6Li NMR spectra.⁶⁵ More recently, larger $^{6,7}\text{Li-H}$ coupling constants (up to 1 Hz) have been reported for the dilithio compound (**7**),⁴¹ the dimer and tetramer of vinyl lithium (**8**),⁷⁹ and the dilithio compound (**9**).⁸⁹ For vinyl lithium, even the relative signs of these coupling constants could be determined from a two-dimensional experiment,⁷⁹ and it was concluded that geminal and vicinal $^6\text{Li-H}$ interactions are positive. In the case of (**9**), the assignment of the nonequivalent lithium resonances in the dimer structure was based on the observed $^6\text{Li-H}$ coupling,⁸⁹ where $^3J(^6\text{Li}, ^1\text{H})$ obeys the Karplus equation (Figure 8).

Figure 4 Isotopic fingerprints in ^6Li NMR spectra: (a) phenyllithium monomer (THF/PMTDA, -122°); (b) phenyllithium dimer (Et_2O /TMEDA, -111°); (c) methylolithium tetramer ($\text{R} = \text{CH}_3$) (Et_2O , -92°); (d) fluxional phenyllithium tetramer (Et_2O , -102°). The measured $^2\text{H}/^1\text{H}$ isotope shifts for $\delta(^6\text{Li})$ are 19.2, 10.4, 15.6, and 7.0 ppb, respectively. All systems were ^6Li labeled and 50% of the organic ligands were perdeuterated; $\nu_0(^6\text{Li}) = 58.88 \text{ MHz}$

2.4.3.3 ^7Li – ^6Li Coupling. A special case of heteronuclear interactions is the coupling between ^6Li and ^7Li , which has so far not been reported, despite earlier attempts to detect such couplings from partially labeled compounds.⁹⁰ Such interactions are of interest because they should be observed also for chemically equivalent lithium nuclei which

are isochronous in the homonuclear case. From the known magnitude of a ^6Li – ^6Li coupling (see above), one estimates values of about 0.4 Hz.

2.4.3.4 ^{13}C – $^{6,7}\text{Li}$ Coupling. Scalar spin–spin interactions between $^{6,7}\text{Li}$ and ^{13}C lead to coupling constants of sizeable magnitude (3–17 Hz for ^6Li , and larger by a factor of 2.64 for ^7Li) and these interactions have been introduced as valuable parameters for structural determinations of organolithium compounds. After the first detection of such couplings in ^{13}C enriched methylolithium,⁹¹ their potential was soon recognized and initiated (for reasons of improved detectability) the use of ^6Li labeling, introduced by Fraenkel⁹² and Seebach.^{93,94} A large variety of these parameters has been collected over the years for ^6Li labeled systems, where the line splitting due to ^{13}C – ^6Li coupling is measured in the region of slow exchange, usually below -50°C , in the ^1H decoupled ^{13}C NMR spectra (Figure 9). Representative data are shown in Table 5; more extensive collections are given by Thomas²⁴ and Bauer and Schleyer.²⁶ While the magnitude of the coupling is usually easy to establish, the characterization of the multiplets with respect to the number of lines and their intensity distribution is often difficult, because the smaller lines in the wings are hard to detect if the signal-to-noise ratio is low. Even a careful line simulation will not allow distinction between a septuplet and a nonuplet in all cases. Only recently, a positive sign was established for $^1J(^{13}\text{C}, ^6\text{Li})$ in vinylolithium.⁷⁹ It is important to note that ^{13}C – $^{6,7}\text{Li}$ coupling is not observed for organolithium

Figure 5 ^{13}C NMR signal of the lithiated carbon of 1-lithio-2,4,6-tri-*t*-butylbenzene with natural isotopic $^{6,7}\text{Li}$ distribution (THF- d_8 /TMEDA 1:1, -79°). The quadruplet expected for ^{13}C , ^7Li coupling is not resolved (Reproduced with permission from W. Bauer, W. R. Winchester, and P. v. R. Schleyer, *Organometallics*, 1987, **6**, 2371)

Figure 6 ^{13}C satellites (arrows) in the ^6Li NMR spectrum of: (a) $[^6\text{Li}]t$ -butyllithium (1 M in cyclopentane, -40°); (b) $[^6\text{Li}]$ phenyllithium (0.5 M in dimethoxymethane, -73°). The coupling constants are 5.4 and 8.0 Hz, respectively. (Reproduced, in part, with permission from R. D. Thomas, M. T. Clarke, R. M. Jensen, and T. C. Young, *Organometallics*, 1986, **5**, 1851)

compounds with π -bound lithium (benzylolithium, dilithionaphthalene, etc.).

Static aggregates are characterized by coupling to nearest neighbors, while in *fluxional aggregates* remote nuclei are also involved. An empirical rule^{23,63,96} for the coupling (in hertz) is

$$J(^{13}\text{C}, ^6\text{Li})_{\text{obs}} \approx 17/n; \quad J(^{13}\text{C}, ^7\text{Li})_{\text{obs}} \approx 45/n \quad (8)$$

where n is the number of equivalently coupled ^6Li nuclei. This leads to values of about 17 Hz for monomers, 8.5 Hz for

dimers, and 5.7 Hz for tetramers and hexamers (see Figure 1). For fluxional tetramers and hexamers these numbers drop to 4.3 and 2.8 Hz, respectively. An important point is that only coupling over one formal ^{13}C – $^{6,7}\text{Li}$ bond has so far been observed. In recent years a number of dilithio compounds have been synthesized which give rise to more complicated spin systems of the $\text{AA}'\text{XX}'$ and ABXY types.^{85,99} Here the simple rule derived for the $(\text{RLi})_n$ type systems breaks down.

2.4.3.5 ^{15}N – ^6Li Coupling. Coupling between ^6Li and ^{15}N ^{100–102} is of similar importance in the field of lithiated amides and nitrogen compounds, as is ^{13}C – ^6Li coupling in the field of carbon compounds. Due to the low natural abundance of ^{15}N (0.37%) and the concentration limits met when low temperature spectra have to be investigated, measurements have been made exclusively on doubly labeled (^6Li and ^{15}N) systems. Selected examples are shown in Table 5. Again, only one-bond coupling has been observed. The magnitude of these couplings is roughly only half that of the analogous ^{13}C – ^6Li coupling constants. An empirical rule analogous to equation (8) can be formulated:²⁶

$$J(^{15}\text{N}, ^6\text{Li})_{\text{obs}} = 7/n \quad (9)$$

2.4.3.6 $^{6,7}\text{Li}$ Coupling to ^{29}Si , ^{31}P , ^{77}Se , ^{119}Sn , and ^{195}Pt . Finally, $^{6,7}\text{Li}$ coupling to ^{29}Si ,¹⁰³ ^{31}P ,^{104–110} ^{77}Se ,¹¹¹ ^{119}Sn ,^{112,113} (^7Li , $J = 6.2$ and 412 Hz), and ^{195}Pt ¹¹⁴ (^7Li , $J = 48$ Hz) has been observed and examples are given in Table 5. The discovery of a 2J coupling between the phosphorus atom of hexamethylphosphoric triamide (HMPTA) and coordinated ^7Li ^{109,110} has been used in an interesting NMR technique for the characterization of lithium ion pair structures.⁶⁸

2.4.4 Scalar Spin–Spin Coupling and Lithium Bonding

Since scalar spin–spin interactions are generally transmitted via chemical bonds, the observation of scalar spin–spin coupling is often taken as experimental proof for the existence of covalent bonding between the nuclei of interest. Streitwieser, however, has pointed out¹¹⁵ that coupling between $^{6,7}\text{Li}$ and, for example, ^{13}C may also be based on electron polarization through space, a mechanism met quite often for coupling of ^{19}F .¹¹⁶ The observation of various $^{6,7}\text{Li}$ – X coupling constants is thus also compatible with a high ionic character of the respective Li – X bond.

As far as $^{6,7}\text{Li}$ – ^{13}C coupling constants are concerned, two facts merit attention: (1) such couplings are observed only to carbon directly bonded to lithium; and (2) they seem to be independent of the s character of the carbon–lithium bond, which is a unique finding for one-bond couplings. As Bauer and Griesinger⁷⁹ have noted, the first observation may be rationalized if one remembers the hierarchy of ^{13}C – ^1H coupling constants ($^1J \gg ^2J, ^3J$). A possible explanation for the second observation comes from results of *ab initio* calculations¹¹⁷ which showed that the product of s character and the carbon–lithium covalent bond order is approximately constant for C – Li bonds in methyllithium, lithioethene, and lithioacetylene. If this product dominates the coupling, constant J values should result.

2.5 Quadrupolar Coupling Constants

The quadrupole splitting constant (QSC), of ^7Li has been used by Jackman¹¹⁸ as an empirical parameter to obtain

structural information on lithium enolates in solution. The QSC is given by

$$\text{QSC} = (1 + \eta^2/3)^{1/2} (e^2 Q q_{zz} / h) \quad (10)$$

where $\eta = (q_{xx} - q_{yy})/q_{zz}$ is the asymmetry parameter, and the q_{ii} are the diagonal elements of the electric field gradient

Figure 9 ^6Li coupled ^{13}C multiplets for various aggregates of organolithium compounds: (a) phenyllithium monomer; (b) *n*-butyllithium dimer; and (c) static and (d) fluxional *t*-butyllithium tetramer. The coupling constants are 14.8, 7.9, 5.4, and 4.1 Hz, respectively. (Reproduced, in part, with permission from R. D. Thomas, M. T. Clarke, R. M. Jensen, and T. C. Young, *Organometallics*, 1986, **5**, 1851)

tensor for the ^7Li nucleus. The other constants are from Table 2. The value of q_{zz} would be of most interest, but cannot be obtained separately. The QSC can thus be treated only as an empirical parameter related to the electrical environment of the ^7Li nucleus, and its experimental determination is possible via relaxation time measurements. If a dominance of quadrupolar relaxation is assumed for ^7Li in molecules in solution, then

$$1/T_1^Q = (2\pi^2/5)(\text{QSC})^2 \tau_c \quad (11)$$

If τ_c can be determined from the dipolar longitudinal relaxation of a ^{13}C nucleus in the same molecule, which has its ^{13}C – ^1H internuclear distance vector collinear or parallel to the assumed direction of q_{zz} , the relationship

$$\text{QSC (kHz)} = 70.0 [T_1(^{13}\text{C})/T_1(^7\text{Li})]^{1/2} \quad (12)$$

can be used to determine the QSC. A further requirement for the applicability of equation (12) is that the ^{13}C – ^1H bond does not reorient independently of q_{zz} by a rate comparable to or greater than the rotational diffusion of the whole molecule, for example by internal molecular motion.

2.6 The $\{^1\text{H}\}^6\text{Li}$ Nuclear Overhauser Effect

An important result of the relaxation studies on ^6Li executed by Wehrli^{7,43} was the finding that an appreciable $\{^1\text{H}\}^6\text{Li}$ NOE exists, being $\eta = 2.61$ and 1.19 for ^6Li in aqueous LiCl and in *n*-butyllithium in *n*-hexane, respectively. The theoretical value is $\eta = \gamma(^1\text{H})/2\gamma(^6\text{Li}) = 3.40$ (Table 2). Due to the inefficient quadrupolar relaxation, the ^6Li nucleus shows considerable dipolar interactions with neighboring protons, and these can yield valuable structural information (see Section 3.2.1). Similar effects for ^7Li are uncommon because of the stronger dominance of quadrupolar relaxation for this nucleus, but appreciable $\{^1\text{H}\}^7\text{Li}$ NOEs have been found for systems such as (**7**).⁴¹ Finally, for ^{13}C enriched systems, NOEs between ^{13}C and ^6Li have been observed¹¹⁹ which are of interest for polyhapto bound lithium where scalar coupling to ^{13}C is absent.

3 EXPERIMENTAL METHODS

The introduction of new one- and two-dimensional experimental techniques and the existence of scalar coupling to ${}^6\text{Li}$ as well as the $\{^1\text{H}\}^6\text{Li}$ NOE have paved the way for new methods of structural elucidation and the study of bonding and dynamics, mainly in the field of organolithium compounds and related systems such as lithiated amides and phosphorus compounds. For ${}^6\text{Li}$, appropriate product operator treatments for various pulse sequences are available which are based on density operators for spin-1 nuclei.^{120,121} With respect to the applicability of the techniques, the natural abundance of the nuclei involved has to be considered in order to decide on the experimental strategy to be used. Experiments which involve rare nuclei such as ${}^{13}\text{C}$ or ${}^{15}\text{N}$ are, therefore, not always feasible for compounds which contain these nuclides in natural abundance, and require appropriate labeling.

3.1 Methods Based on Coherent Magnetization Transfer by Scalar Spin–Spin Coupling

3.1.1 Experiments Based on Homonuclear Spin–Spin Coupling

3.1.1.1 ${}^6\text{Li}$ – ${}^6\text{Li}$ and ${}^7\text{Li}$ – ${}^7\text{Li}$ COSY Experiments. An attractive feature of the two-dimensional Jeener experiment¹²² is its sensitivity for small scalar interactions which give rise to cross peaks even if line splittings in the corresponding one-dimensional spectra are not resolved. This was first demonstrated for the ${}^1\text{H}$ NMR spectrum of a paramagnetic nickel complex¹²³ and for quadrupolar nuclei in the case of ${}^{11}\text{B}$.¹²⁴ The first successful ${}^6\text{Li}$ – ${}^6\text{Li}$ COSY-90 experiment was reported in 1986.⁸¹ It yielded direct evidence for the existence of homonuclear ${}^6\text{Li}$ – ${}^6\text{Li}$ couplings. Since the magnitude of these interactions is small (see above), improvements are possible if, instead of the COSY-90, the COSY-LR sequence¹²⁵ developed for the detection of long range couplings is used. In addition, a 45° pulse¹²⁵ serves as a mixing pulse in order to reduce the intensity of the diagonal signals:

$$90^\circ - t_1 -, \Delta, 45^\circ, \Delta, \text{FID}(t_2) \quad (13)$$

The importance of this experiment for structural research must be seen in the possibility of distinguishing ${}^6\text{Li}$ signals which belong to nonequivalent lithium sites in one particular cluster from those ${}^6\text{Li}$ signals which arise from lithium atoms in different clusters (Figure 10).

A similar experiment for ${}^7\text{Li}$ yields less unambiguous results, because for small chemical shifts signal overlap may lead to the detection of artificial cross peaks.¹²⁶ This was later shown by the application of a ${}^7\text{Li}$ – ${}^7\text{Li}$ COSY-DQF experiment, where the double quantum filter (DQF) eliminates the artifacts.¹²⁷ Recently, a genuine ${}^7\text{Li}$ – ${}^7\text{Li}$ COSY experiment was successfully performed for the nonequivalent ${}^7\text{Li}$ nuclei in the dimer of (Z)-2-lithio-1-(*o*-lithiophenyl)ethene (**9**),⁸⁴ where the chemical shift between the nonequivalent lithium sites is sufficiently large to avoid line overlap.

Experimentally, modern software allows ${}^6,7\text{Li}$ – ${}^6,7\text{Li}$ COSY spectra to be recorded in the phase-sensitive mode. Nevertheless, the fine structure in the cross peaks and diagonal peaks, which was calculated by the product operator formalism,¹²⁰

Figure 10 ${}^6\text{Li}$ – ${}^6\text{Li}$ COSY spectrum for the mixture of monomer and dimer of (*E*)-2-lithio-1-phenyl-1-(*o*-lithiophenyl)pent-1-ene (**10**) recorded with the pulse sequence of equation (13)

has been resolved only once⁸⁴ because of the small magnitude of the homonuclear coupling constants involved.

3.1.1.2 ${}^6\text{Li}$ – ${}^6\text{Li}$ and ${}^7\text{Li}$ – ${}^7\text{Li}$ INADEQUATE Experiments. The direct detection of a homonuclear ${}^6\text{Li}$ – ${}^6\text{Li}$ coupling in the case of (*E*)-2-lithio-1-phenyl-1-(*o*-lithiophenyl)pent-1-ene⁸² [(**10**), see Figure 10] initiated the experimental realization of one- as well as two-dimensional ${}^6\text{Li}$ – ${}^6\text{Li}$ INADEQUATE experiments.⁸³ Both experiments were performed with the standard pulse sequences available^{129,130} and yielded an unequivocal assignment of the respective ${}^6\text{Li}$ – ${}^6\text{Li}$ spin systems, which are of the AA'XX' type in the compounds studied. The antiphase character of the detected magnetization proves to be advantageous for the observation of the small ${}^6\text{Li}$ – ${}^6\text{Li}$ interactions, where single quantum magnetization does not interfere because of isotopic ${}^6\text{Li}$ enrichment. In addition, the chemical shift difference is a less critical parameter than in the COSY experiment. Due to the relatively short experimental time necessary, the one-dimensional INADEQUATE experiment is by far the most attractive choice for the detection of coupled, nonequivalent lithium nuclei in organolithium aggregates. An example is shown in Figure 11. In an analogous way,

Figure 11 One-dimensional ${}^6\text{Li}$ - ${}^6\text{Li}$ INADEQUATE spectrum of a mixture of the dimer and monomer of (E)-1-lithio-2-(2-lithiophenyl)-1-phenylhex-1-ene (11) which identifies the signals that belong to the ${}^6\text{Li}$ - ${}^6\text{Li}$ AA'XX' system of the dimer. (Reproduced with permission from O. Eppers, T. Fox, and H. Günther, *Helv. Chim. Acta*, 1992, **75**, 883)

successful one- and two-dimensional ${}^7\text{Li}$ - ${}^7\text{Li}$ INADEQUATE experiments have been performed with compound (9).⁸⁴

An interesting feature of two-dimensional INADEQUATE experiments with spin-1 nuclei is the observation of signals which arise from one-spin double quantum coherences in addition to those which originate from two-spin double quantum coherences.^{131,132} Such signals have the coordinates $\omega_1 = 2\omega_i$, $\omega_2 = \omega_i$ and do not yield correlation information. They have been observed in ${}^2\text{H}$ - ${}^2\text{H}$ ^{131,132} as well as ${}^6\text{Li}$ - ${}^6\text{Li}$ two-dimensional INADEQUATE experiments.¹³³

3.1.2 Experiments Based on Heteronuclear Spin-Spin Coupling

3.1.2.1 One-Dimensional Spin Echo Experiments. The gated decoupler technique has been used in the manner similar to the well-documented experiments for ${}^2\text{H}$ -substituted carbon atoms¹³⁴ in order to edit signals of ${}^{13}\text{C}$ - ${}^6\text{Li}$ spin systems with different multiplicity for the ${}^{13}\text{C}$ signals.¹³⁵ Phase selection for ${}^{13}\text{C}$ signals is then achieved with gated ${}^6\text{Li}$ decoupling, where the intensity of the detected ${}^{13}\text{C}$ signal from ${}^{13}\text{C}$ - ${}^6\text{Li}_n$ systems for an evolution period of $\tau = 1/2J({}^{13}\text{C}, {}^6\text{Li})$ is governed by

the equation

$$I = I_0(-1/3)^n \quad (14)$$

Practical applications are limited by the fact that for $n = 3$ the ${}^{13}\text{C}$ signal intensity is already rather weak and the signal virtually disappears for $n > 3$. The low natural ${}^{13}\text{C}$ abundance further complicates the situation. An interesting variation of the experiment, however, which works well for alkyllithium systems with relatively long ${}^{13}\text{C}$ relaxation times T_1 and T_2 is the observation of the totally refocused ${}^{13}\text{C}$ magnetization after the evolution delay $\tau = 1/J_{\text{obs}}$ with, according to equation (8), $\tau = k/17$ for monomers ($k = 1$), dimers ($k = 2$), and tetramers ($k = 3$).¹³⁶ As shown in Figure 12, this allows the selection of ${}^6\text{Li}$ signals of individual aggregates.

3.1.2.2 Two-Dimensional J-Resolved ${}^{13}\text{C}$ - ${}^6\text{Li}$ and ${}^{31}\text{P}$ - ${}^7\text{Li}$ Spectroscopy. Introducing a variable evolution time τ , a series of experiments with gated ${}^6\text{Li}$ decoupling leads to J-resolved ${}^{13}\text{C}$ spectra where the ${}^{13}\text{C}$ - ${}^6\text{Li}$ multiplets appear parallel to the F_1 axis.²³ A similar experiment has been applied to ${}^{31}\text{P}$ - ${}^7\text{Li}$ spin systems to separate the ${}^{31}\text{P}$ - ${}^7\text{Li}$ coupling constants from the homonuclear ${}^{31}\text{P}$ - ${}^{31}\text{P}$ interactions in lithiated organophosphorus compounds.¹⁰⁴

3.1.2.3 Two-Dimensional Shift Correlations. Two-dimensional shift correlations certainly belong to the most important experimental techniques available for structure

Figure 12 $J({}^{13}\text{C}, {}^6\text{Li})$ -modulated ${}^{13}\text{C}$ spin echo spectra of ${}^{13}\text{C}$ -1 signals for oligomers of $[\text{}^6\text{Li}]t$ -butyllithium (cyclopentane/ether, -60°): (a) multiplets for dimer and tetramer (see Table 5); (b) ${}^6\text{Li}$ decoupled spectrum; (c) selection of the dimer signal with $\tau = 128$ ms ($J = 7.8$ Hz); (d) selection of the tetramer signal with $\tau = 184$ ms ($J = 5.4$ Hz). (Reproduced with permission from R. D. Thomas and D. H. Ellington, *Magn. Reson. Chem.*, 1989, **27**, 628)

elucidation. This is also true for organometallic compounds and related systems, where quite a number of ${}^6\text{Li}$ -X correlation experiments have been performed. As is well known from ${}^{13}\text{C}$ - ${}^1\text{H}$ experiments, there are two alternative methods for two-dimensional shift correlations: the standard heteronuclear correlation experiment based on polarization transfer¹³⁷ (HETCOR),

$$I \quad 90_x^\circ \text{-----} t_1 \text{-----} | \text{-----} \Delta_1 \text{-----} 90_y^\circ, \text{BB} \quad (15a)$$

$$S \quad \text{-----} 180_x^\circ \text{-----} | \text{-----} \text{-----} 90_x^\circ, \text{FID}(t_2) \quad (15b)$$

and the heteronuclear multiple quantum experiment¹³⁸ (HMQC)

$$I \quad 90_x^\circ \text{-----} \Delta_1 \text{-----} | \text{-----} 180_x^\circ \text{-----} \text{FID}(t_2) \quad (16a)$$

$$S \quad \text{-----} \text{-----} 90_x^\circ \text{-----} t_1 \text{-----} 90_\phi^\circ \quad (16b)$$

where $\Delta_1 = 1/2J$. For spin-1 nuclei, appropriate product operator treatments of these experiments have been given.^{17,128,139,140} Both sequences can be performed with ${}^6,{}^7\text{Li}$ as the I or S spin. This choice is determined by the relative magnitude of the γ factors as well as by the isotopic abundance of the two spins.

While the power of these two-dimensional experiments is unquestioned, it should be pointed out that in a number of cases single frequency X decoupling with ${}^6,{}^7\text{Li}$ observation or the corresponding inverse experiments (X observation with selective ${}^6,{}^7\text{Li}$ decoupling) may give the desired information equally well in a relatively straightforward way, especially if only a few, well-resolved ${}^6,{}^7\text{Li}$ resonances exist.

Since ${}^6\text{Li}$ - ${}^1\text{H}$ spin-spin coupling constants are seldom resolved and their existence is often only apparent from line-broadening effects, ${}^6\text{Li}$ - ${}^1\text{H}$ shift correlation experiments have been performed only recently on compounds which show relatively large (of the order of 0.5 Hz) ${}^6\text{Li}$ - ${}^1\text{H}$ coupling constants. Using the simple pulse sequence^{137b}

$$90^\circ(I) - t_1 - \phi(I), 90^\circ(S), \text{FID}(S)(t_2) \quad (17)$$

with ${}^6\text{Li}$ detection, which yields fully coupled two-dimensional ${}^6\text{Li}$ - ${}^1\text{H}$ shift correlations, Bauer and Griesinger⁷⁹ were able to determine the magnitude and sign of all ${}^6\text{Li}$ - ${}^1\text{H}$ coupling constants in the dimer and tetramer of vinyl lithium by applying pulses with angles $\theta < 90^\circ$. For compound (9), ${}^6\text{Li}$ - ${}^1\text{H}$, shift correlation experiments were successful with the standard polarization transfer experiment [HETCOR, equations (15a) and (15b)] as well as with the inverse techniques based on multiple quantum coherences [HMQC, equations (16a) and (16b)].⁸⁹ The latter experiment also yielded splittings in the F_2 dimension which are due to homonuclear ${}^6\text{Li}$ - ${}^6\text{Li}$ couplings.

${}^{13}\text{C}$ - ${}^6\text{Li}$ shift correlation experiments are of vital importance for the assignment of ${}^{13}\text{C}$ and ${}^6\text{Li}$ resonances in organolithium clusters. They are based exclusively on one-bond ${}^{13}\text{C}$ - ${}^6\text{Li}$ couplings (see above) and can be performed in their simplest version as selective ${}^{13}\text{C}$ - ${}^6\text{Li}$ decoupling experiments. One way is to employ selective ${}^6\text{Li}$ decoupling to locate the corresponding ${}^{13}\text{C}$ neighbor. The alternative experiment, selective ${}^{13}\text{C}$ decoupling, is generally only feasible for ${}^{13}\text{C}$ -enriched materials, because otherwise the ${}^{13}\text{C}$ satellites in the ${}^6\text{Li}$ spectrum have to be observed.

Figure 13 Two-dimensional ${}^{13}\text{C}$ - ${}^6\text{Li}$ HMQC NMR shift correlation for 3,4-dilithio-2,5-dimethylhexa-2,4-diene (12) and X-ray structure. The cross peaks show that the carbon atoms of the 'inner' ligands couple exclusively to the 'inner' ${}^6\text{Li}$ sites, while the carbon atoms of the 'outer' ligands couple to both the 'inner' and the 'outer' ${}^6\text{Li}$ nuclei. (Reproduced with permission from D. Moskau, F. Brauers, H. Günther, and A. Maercker, *J. Am. Chem. Soc.*, 1987, **109**, 5532)

For the more elegant two-dimensional ^{13}C – ^6Li shift correlations, which are indispensable in cases of low signal resolution, both pulse sequences shown above [equations (15a) and (15b) and equations (16a) and (16b)] were successfully employed with compounds that contained ^{13}C in natural abundance.^{24,141} Since the γ factors for ^6Li and ^{13}C are not very different, the choice of the nucleus to be detected is not very critical. If ^6Li is decoupled, however, as in the HETCOR sequence with $I = ^6\text{Li}$ and $S = ^{13}\text{C}$, a relaxation delay is necessary for the recovery of I spin magnetization due to the longer ^6Li relaxation times. The HMQC experiment is especially easy to perform with a triple resonance probehead which has, apart from the ^1H and the ^2H lock channel, a fixed frequency for ^{13}C detection and a variable X frequency. An example of the experiment is shown in Figure 13. It is of interest to note that ^{13}C – ^6Li cross peaks can also be observed in cases where

the corresponding ^{13}C – ^6Li coupling is not resolved in the one-dimensional spectrum.²⁴ A similar situation was met for homonuclear $^{6,7}\text{Li}$ – $^{6,7}\text{Li}$ couplings with the COSY experiment (see above).

The ^{15}N – ^6Li HMQC experiment was introduced by Collum for ^6Li and ^{15}N labeled samples of lithiated amines.¹⁴⁰ An example, which highlights the power of the two-dimensional method with respect to single frequency one-dimensional decoupling experiments is given in Figure 14.

An ingenious application of the HMQC experiment for ^{15}N – ^6Li doubly labeled organonitrogen compounds in the form proposed by Müller^{138a} and Bodenhausen and Ruben¹⁴² has been introduced by Gilchrist and Collum,¹⁴³ who showed that the method allows—on the basis of homonuclear ^{15}N zero-quantum coherence selection—discrimination between symmetric cyclic dimers and higher oligomers of lithiated

Figure 14 ^{15}N – ^6Li HMQC spectrum of a sample of $[^6\text{Li}, ^{15}\text{N}]$ lithium tetramethylpiperidine (0.1 M in 3:1 THF/pentane, -120°) with one equivalent of added $^6\text{LiBr}$ showing cross peaks for the monomer (13), the dimer (14), and the mixed aggregates (15) and (16). (Reproduced with permission from J. H. Gilchrist, A. T. Harrison, D. J. Fuller, and D. B. Collum, *Magn. Reson. Chem.*, 1992, **30**, 855)

Figure 15 ^6Li -detected ^{15}N zero quantum NMR spectra of: (a) $[\text{}^6\text{Li},^{15}\text{N}]$ lithium tetramethylpiperidine (0.1 M in 3:1 THF/pentane, -115°); (b) the same compound dissolved in benzene (0.25 M, 30°). In (b), the 1:2:3:2:1 splitting pattern along F_1 is consistent with a higher oligomer of type (18) rather than the dimer. (Reproduced with permission from J. H. Gilchrist and D. B. Collum, *J. Am. Chem. Soc.*, 1992, **114**, 795)

amines.¹⁴³ This results from the fact that in the dimer (17), which gives rise to an A_2X_2 spin system, both ^6Li spins are coupled to both ^{15}N spins and the sum of the effective ^{15}N – ^6Li coupling is zero,¹²⁰ while in a cyclic trimer or a higher cyclic oligomer (18) not all ^6Li spins couple to a certain ^{15}N spin, the spin system being of the $\text{AA}'\text{A}''\text{XX}'$ type with $J(\text{A}',\text{X}') = J(\text{A}'',\text{X}) = 0$. The nonequivalence of the neighboring ^6Li nuclei then leads to a 1:2:3:2:1 line splitting in the F_1 dimension (Figure 15).

The utility of the HMQC experiment for structure determinations in organometallic compounds has been extended by the introduction of the ^{31}P – ^6Li shift correlation experiment,¹⁴⁴ which is based on scalar coupling between lithium and the phosphorus in HMPTA. Here, detection of the sensitive ^{31}P nucleus, having short relaxation times, is of advantage.

The development of rotating frame experiments for the liquid phase¹⁴⁵ has produced a number of interesting homo- and heteronuclear pulse sequences with great potential for practical applications which are generally known as homo- and heteronuclear TOCSY experiments. Among these, TOCSY (total correlation spectroscopy)¹⁴⁵ has found widespread use. Homonuclear one- and two-dimensional TOCSY experiments with spin-1 nuclei have been performed for deuterium^{146,147} and the heteronuclear ^6Li –X TOCSY experiment

$$I \quad 90^\circ\text{-----}t_1\text{-----}, \text{MLEV16} \quad (18a)$$

$$S\text{-----}180^\circ\text{-----}, \text{MLEV16, FID}(t_2) \quad (18b)$$

has been tested for ^7Li – ^1H as well as ^6Li – ^1H shift correlations.^{84,148} The MLEV16 decoupling sequence¹⁴⁹ was

Figure 16 ^6Li – ^1H HETERO TOCSY experiment for the phenyl-lithium dimer (0.3 M in THF, -70°), showing cross peaks for the *ortho* and *meta* protons

used for magnetization transfer and $^6,7\text{Li}$ as well as ^1H detection was successful. A ^6Li – ^1H TOCSY experiment for phenyl-lithium, where magnetization transfer is detected up to the *meta* protons, is shown in Figure 16. An advantage of these experiments as compared with correlation experiments based on the sequences shown in equations (15a) and (15b) and equations (16a) and (16b) must be seen in the fact that pure absorption spectra are produced. Signal elimination as a consequence of small coupling constants, as observed for antiphase cross peaks, is thus prevented.

3.2 Methods Based on Incoherent Magnetization Transfer

3.2.1 $\{^1\text{H}\}^6\text{Li}$ Nuclear Overhauser Spectroscopy

The great potential of the $\{^1\text{H}\}^6\text{Li}$ NOE, discovered by Wehrli,^{7,43} for structural research was recognized in 1986 independently by two groups. Avent et al.¹⁵⁰ reported one-dimensional NOE difference experiments for hydrido[tris(trimethylsilyl)methyl]metalates, while Bauer et al.¹⁵¹ introduced the $\{^1\text{H}\}^6\text{Li}$ HOESY (heteronuclear Overhauser) experiment. The pulse sequence for these types of experiment,

$$I \quad 90^\circ\text{-----}t_1\text{-----}90^\circ\text{-----}t_M\text{-----}| \text{--- BB ---} \quad (19a)$$

$$S \quad \text{-----}180^\circ\text{-----}| \text{-----}90^\circ, \text{FID}(t_2) \quad (19b)$$

was proposed in 1983 independently by Rinaldi¹⁵² and Yu and Levy¹⁵³ for ^{13}C – ^1H and ^{31}P – ^1H spin pairs, but had not found widespread use. In particular, in the ensuing years Bauer et al. developed ^1Li – ^1H HOESY measurement into a valuable

Figure 17 Two-dimensional $\{^1\text{H}\}^6\text{Li}$ HOESY spectrum of 2-lithio-1-phenylpyrrole/TMEDA (THF, -70°). Short $^6\text{Li}-^1\text{H}$ distances are indicated by cross peaks for H-3, H-7, H-11, and the CH_3 protons of the TMEDA ligand. (Reproduced with permission from W. Bauer, G. Müller, R. Pi, and P. v. R. Schleyer, *Angew. Chem.*, 1986, **98**, 1130)

tool for the detection of small $^6\text{Li}-^1\text{H}$ distances.^{26,28,154,155} The advantage of the two-dimensional experiment is obvious if several $^6\text{Li}-^1\text{H}$ contacts exist (Figure 17), while the higher sensitivity and resolution attainable in one-dimensional NOE difference experiments often is of practical importance.¹⁵⁶

$\{^1\text{H}\}^6\text{Li}$ NOE effects are also observed for the protons of TMEDA ligands (Figure 17) and those of solvent molecules, and can thus give interesting information about solvation phenomena. In addition, $\{^1\text{H}\}^6\text{Li}$ HOESY spectroscopy is a valuable tool for the study of ion pairs.¹⁵⁷ Even $\{^1\text{H}\}^7\text{Li}$ HOESY experiments are feasible in special cases where

molecular symmetry around the ^7Li nucleus reduces its quadrupolar relaxation rate.⁴² Qualitative and quantitative information on $^6,7\text{Li}-^1\text{H}$ distances have been obtained from cross-peak buildup rates,^{42,150,158} where the scaling was derived from a bond length determined by X-ray diffraction of the solid. It is noteworthy that $\{^1\text{H}\}^6\text{Li}$ HOESY spectra can be successfully recorded for compounds with natural ^6Li abundance. Finally, a $^{13}\text{C}-^6\text{Li}$ HOESY experiment has been performed for benzyl lithium compounds,¹¹⁹ but it requires ^{13}C labeling and can thus be applied only in selected cases.

3.2.2 Dynamic $^6,7\text{Li}$ NMR Spectroscopy and $^6,7\text{Li}-^6,7\text{Li}$ Two-Dimensional Exchange (EXSY) Spectroscopy

The dynamic nature of most organolithium compounds in solution forms the basis for broad applications of dynamic NMR (DNMR) in this field. Lineshape changes are observed for all relevant nuclei (^1H , $^6,7\text{Li}$, ^{13}C , and ^{31}P) and can potentially be used for qualitative and quantitative analysis of the dynamic processes involved.^{32,77,78,159,160} $^6,7\text{Li}$ spectra are favorable because line splittings due to scalar coupling are absent and the number of signals is usually low. The standard techniques available for DNMR investigations¹⁶¹ are today supplemented by two-dimensional methods, where the two-dimensional EXSY experiment^{162,163}

$$90^\circ - t_1 - 90^\circ - t_M - 90^\circ, \text{FID}(t_2) \quad (20)$$

can be applied to systems which are in slow exchange. $^6,7\text{Li}$ EXSY spectra^{23,57,85} yield important information about the dynamic process responsible for the lineshape changes and the exchange mechanisms involved (Figure 18). Using the appropriate equations,¹⁶²⁻¹⁶⁴ rate constants can be obtained from the relative intensities of the cross peaks and diagonal peaks.

Figure 18 Two-dimensional EXSY ^6Li NMR spectra of a mixture of *n*-butyl- and phenyllithium (BuLi and PhLi) in the presence of TMEDA, which documents ^6Li exchange between dimers of BuLi and PhLi and the mixed aggregate BuLi/PhLi, and additional ^6Li exchange between $(\text{BuLi})_2$ and $(\text{PhLi})_2$ ¹⁶⁵

1 INTRODUCTION

The use of metal containing compounds in medicine and health applications has been practiced for several thousand years.¹ The Egyptians used copper to sterilize water in 3000 BC and the Chinese were using gold in a variety of medicines 3500 years ago. In fact, the first modern chemotherapeutic agent was an organoarsenic compound (Erlisch's arsphenamine), although modern pharmaceuticals are dominated by organic compounds. The success of cisplatin as an anticancer drug has largely stimulated the modern use of metal compounds for therapy and diagnosis. Beside platinum, clinically useful metal compounds include gold in antiarthritic agents, lithium for manic depression, antimony in antileishmaniasis, bismuth in antiulcer drugs, gadolinium (Gd^{3+}) as a magnetic resonance imaging contrast agent and technetium ($^{99\text{m}}\text{Tc}$) as radio-diagnostic agents (Table 1).^{1–4} Not only do inorganic compounds extend the range of drugs available, but they are also successful in treating some diseases where organic compounds are not.

Both the metal and the bound ligands determine the biological activity of metallodrugs, not just the metal. The active species may not be that which is administered or tested in vitro, and it may be biotransformed by ligand substitution and/or redox reactions before it reaches the target sites. It is important to investigate both kinetic (ligand-exchange dynamics, mechanism and pathway) and thermodynamic aspects of the reactivity of a metal compound since biological systems are rarely at thermodynamic equilibrium. Modern multinuclear and multidimensional NMR spectroscopy is a very powerful method for investigation of the speciation of metal complexes in solution, and to a lesser extent in the solid-state, and is applicable for studies of the interaction of metal compounds with biomolecules under physiologically relevant conditions.

Although almost all of the available NMR techniques have been used for studying metallodrugs, ^1H NMR spectroscopy

continues to be the most widely used method for monitoring the behavior of ligands and biomolecules. Other spin 1/2 nuclei such as ^{13}C , ^{15}N , ^{31}P and ^{195}Pt , and weak quadrupolar nuclei (e.g., ^6Li , ^7Li , ^{27}Al and ^{51}V , Table 2) have also quite often been used and ^7Li will be discussed in a later section. Most medically relevant metals are quadrupolar nuclei. Antimony, bismuth and gold have a limited number of useful NMR isotopes. This situation may improve at very high fields (e.g., 14.1 T and over), which are expected to dramatically sharpen the central transition ($m = 1/2$ to $-1/2$) of half-integer quadrupolar nuclei such as ^{27}Al ($I = 5/2$), ^{45}Sc ($I = 7/2$) and ^{71}Ga ($I = 3/2$), Table 2.⁵ Other candidates include biologically important elements, e.g., ^{25}Mg , ^{43}Ca and ^{67}Zn . In the limit of slow isotopic molecular motion (e.g., macromolecules, $\omega\tau_c \gg 1$), the linewidth ($\Delta\nu_{1/2}$) of the central transition ($m = 1/2$ to $-1/2$) decreases with increasing magnetic field:

$$\Delta\nu_{1/2} = k \left[\frac{\chi^2}{\tau_c \nu_0^2} \right] \quad (1)$$

where χ is the quadrupolar coupling constant ($\chi = e^2qQ/h$), τ_c is the correlation time for fluctuations in the electric field gradient at the nucleus and ν_0 is the resonance frequency which is proportional to the magnetic field. Decreasing temperature and increasing viscosity also give rise to a decrease in linewidths.⁶ In these quadrupolar systems, the apparent shift is field-dependent, in contrast to $I = 1/2$ nuclei. The second-order dynamic frequency shift is given by:^{7,8}

$$\Delta\delta_d = \delta_{\text{obs}} - \delta_{\text{iso}} \left(m = \frac{1}{2} \text{ to } -\frac{1}{2} \right) = k \left(\frac{\chi^2}{\nu_0^2} \right) \quad (2)$$

The chemical shift of ^{71}Ga in ovotransferrin, for example, is -103 ppm at 11.7 T but -57 ppm at 17.6 T.^{5b}

This article provides examples of the application of NMR spectroscopy to the speciation of metallopharmaceuticals in solution and in the solid-state including biofluids and cells, and complexation to biomolecules (nucleic acids, peptides and proteins). Since the topic is vast, we focus on platinum anticancer, gold antiarthritic, lithium and bismuth antiulcer drugs. The reader is referred to related papers in this encyclopedia and elsewhere.⁹

2 PLATINUM (AND OTHER METALLO) ANTICANCER DRUGS

The accidental observation of the inhibition of bacterial division by *cis*-diamminedichloroplatinum(II) (cisplatin, *cis*- $\text{Pt}(\text{NH}_3)_2\text{Cl}_2$ or *cis*-DDP) in 1965 by Rosenberg led to the antiproliferative effects of this compound being applied to therapy of human tumours.^{10–12} Today cisplatin is among the most active and widely used anticancer drugs, together with the second-generation drug carboplatin $\text{Pt}(\text{NH}_3)_2(\text{CBDCA}-\text{O},\text{O}')$, where CBDCA is cyclobutane-1,1-dicarboxylate). Two new platinum compounds nedaplatin and oxaliplatin have recently been approved for clinical use in Japan and France, respectively (Scheme 1). Ru^{3+} compounds and the organometallic complex titanocene dichloride also have promising anticancer activities.

2 BIOCHEMICAL APPLICATIONS

Table 1 Some metallodrugs and diagnostic agents

Compounds	Product	Use	Transformation events	Biological targets
Li_2CO_3	Camcolit	Manic depression	Widely distributed in body	Enzymes in inositol phosphate pathways
$\text{Na}_2[\text{Fe}^{\text{II}}(\text{NO})(\text{CN})_5]$	Nipride	Hypotensive crisis (vasodilator)	Release of CN^- , reaction with thiols	Release of NO to guanylate cyclase
Zn^{II} pyridothione	Omadine	Antimicrobial (antidandruff)		Skin
$^{67}\text{Ga}^{\text{III}}$ citrate	Neoscan	Diagnostic radio-imaging	Transferrin	Tumors and inflammatory lesions
$^{99\text{m}}\text{Tc}^{\text{V}}_{-\text{D,L-HM-PAO}^{\text{a}}}$	Ceretec	Diagnostic radio-imaging	Ligand exchange?	Brain
$^{99\text{m}}\text{Tc}^{\text{I}}[(\text{C}\equiv\text{N-R})_6]^+{}^{\text{b}}$	Cardiolite	Diagnostic radio-imaging	Potassium channel?	Myocytes (heart)
Ag^{I} sulfadiazine	Flamazine	Antibacterial (burn wounds)	Protein binding	Enzymes (e.g., phosphomannose isomerase), cell walls?
$\text{Na}[\text{Sb}^{\text{V}}\text{stibogluconate}]$	Pentostam	Antileishmanial	Unknown	Parasites in liver
BaSO_4	Baridol	X-ray contrast agent	None (insoluble in water)	Passage through GI tract
$[\text{Gd}^{\text{III}}(\text{DTPA})](\text{meglumine})_2$	Magnevist	MRI contrast agent	None	Extracellular water
$[\text{Gd}^{\text{III}}(\text{DOTA})]^-$	Dotarem	MRI contrast agent	None	Extracellular water
<i>cis</i> - $[\text{Pt}^{\text{II}}\text{Cl}_2(\text{NH}_3)_2]$	Cisplatin	Anticancer	Hydrolysis, L-Met adducts and GSH	DNA
$\text{Pt}^{\text{II}}[(\text{CBDCA})(\text{NH}_3)_2]^{\text{c}}$	Carboplatin	Anticancer	L-Met adducts, ring open and release of CBDCA, and GSH	DNA
Au^{I} thiomalate	Myocrisin	Antiarthritic drug	Thiol exchange, MT, albumin (Cys^{34}), oxidation to Au^{III} ?	Lysosomes (aurosomes), thiol group of proteins
$\text{Et}_3\text{P Au}^{\text{I}}(\text{acetylthioglucose})$	Auranofin	Oral antiarthritic drug	Phosphine oxidation, Au^{I} to Au^{III} ?	Lysosomes (aurosomes), thiol group of proteins
Colloidal Bi^{III} citrate	De-Nol	Antiulcer and antimicrobial	GSH, MT and transferrin?	Block Fe^{III} uptake? enzymes in <i>Helicobacter pylori</i> ?
Ranitidine Bi^{III} citrate	Pylorid	Antiulcer and antimicrobial	GSH, MT and transferrin?	Block Fe^{III} uptake? enzymes in <i>Helicobacter pylori</i> ?

^aHM-PAO is hexamethyl propyleneamine oxime.

^b $\text{C}\equiv\text{N-R}$ represents 2-methoxyisobutylisocyanide.

^cCBDCA is 1,1-dicarboxycyclobutane.

Table 2 Useful NMR properties of selected elements

Nucleus	Spin	Natural abundance (%)	Quadrupole moment (10^{-28} m)	Receptivity/ ^{13}C	NMR Frequency (100 MHz ^1H)
^6Li	1	7.42	-6.4×10^{-4}	3.58	14.717
^7Li	3/2	92.58	-3.7×10^{-2}	1.54×10^3	38.864
^{13}C	1/2	1.108		1	25.145
^{14}N	1	99.63	1.6×10^{-2}	5.7	7.224
^{15}N	1/2	0.37		2.2×10^{-2}	10.136
^{25}Mg	5/2	10.00	0.1999	1.54	6.126
^{27}Al	5/2	100	0.140	1.17×10^3	26.077
^{31}P	1/2	100		3.77×10^2	40.480
^{51}V	7/2	99.76	-5.2×10^{-2}	2.16×10^3	26.350
^{67}Zn	5/2	4.11	0.150	0.665	6.252
^{69}Ga	3/2	60.40	0.168	2.38×10^2	24.040
^{71}Ga	3/2	39.60	0.106	3.19×10^2	30.495
^{109}Ag	1/2	48.18		0.276	4.653
^{195}Pt	1/2	33.8		19.1	21.414

Scheme 1 Structures of clinically used platinum compounds. The carbons marked with asterisks are chiral carbons (Oxaliplatin contains *R,R*-1,2-diaminocyclohexane)

2.1 ^{195}Pt , ^{15}N NMR and Inverse $[^1\text{H}$, $^{15}\text{N}]$ NMR Spectroscopy

In addition to ^1H NMR, the use of ^{15}N and ^{195}Pt NMR spectroscopy has made an important impact, along with other biophysical techniques, in the understanding of the mode of action of platinum anticancer drugs. This includes the detection of intermediates arising during the hydrolysis process and in reactions with either DNA or amino acids (peptides and proteins), and metabolites in body fluids.⁹ ^{195}Pt ($I = 1/2$) is a reasonably sensitive nucleus for NMR detection with natural abundance of 33.8% (Table 2) and a receptivity relative to ^1H of 3.4×10^{-3} . The spin-relaxation time for ^{195}Pt is usually in the range of 0.014–8.3 s, with most values less than 2 s.¹³ The short relaxation times (T_1) are attributed to efficient relaxation via the chemical shift anisotropy (CSA) and spin-rotation (SR) contributions. The advantage of the increased sensitivity achievable at high magnetic field for ^{195}Pt is offset by the increase in linewidths due to CSA relaxation ($\propto B_0^2 \tau_c$). Similarly, ^{195}Pt satellites in either ^1H or ^{15}N spectra of Pt^{2+} complexes are often broadened beyond detection at high fields,

again due to CSA relaxation of ^{195}Pt , which excludes the use of $[^1\text{H}$, $^{195}\text{Pt}]$ inverse detection to enhance the sensitivity of detection. The low detection limit (ca. 10 mM) precludes detection of natural abundance ^{195}Pt signals under biologically relevant conditions (e.g., in body fluids), but can be enhanced by isotopic enrichment of ^{195}Pt to >95%. A previous report has shown that DNA platination at millimolar concentrations can readily be studied with ^{195}Pt enrichment and both mono- and bi-functional guanine adducts were detected (Scheme 2 and Figure 1).¹⁴ The rate-determining step for initial binding of cisplatin was found to be hydrolysis of the first chloride and similarly the rate-determining step for closure of the monofunctional species to form bifunctional adducts was found to be hydrolysis of the second chloride.

The chemical shift range of ^{195}Pt is very large (15 000 ppm and usually in the range from –6000 to 9000 ppm). Ready differentiation between Pt^{2+} and Pt^{4+} is usually possible. The former (Pt^{2+}) tends to have chemical shifts at the higher field while the latter resonates in the low-field end of the range. The ^{195}Pt chemical shift in monomeric compounds is usually highly sensitive to the nature of bound donor atoms and can

Scheme 2 Structures of cisplatin aqua-chloro intermediate, mono- and bi-functional DNA adducts

Figure 1 Time-dependent ^{195}Pt NMR spectra of the reaction between cisplatin and chicken erythrocyte DNA at 37 °C in 3 mM NaCl, 1 mM NaH_2PO_4 . (Adapted with permission from Ref.¹⁴)

Table 3 ^{195}Pt chemical shifts of *cis*-Pt complexes with different donor atoms

<i>Cis</i> -Pt complexes	$\delta(^{195}\text{Pt})$ range ^a	References
<i>cis</i> -[Pt(NH ₃) ₂ Cl ₂]	−2048 to −2168 ^b	14,15
<i>cis</i> -[Pt(NH ₃) ₂ Cl(O)]	−1806 to −1841	16

be used as a diagnostic tool to distinguish various types of ligand binding to platinum (Table 3).^{15–21} Moreover, the ^{195}Pt chemical shifts are very sensitive to complex geometry, e.g., geometrical isomers and diastereomers, and can be utilized in the detection of different intermediates formed during the reaction of platinum complexes with biomolecules. ^{195}Pt NMR shifts for conformers of bis-guanine derivatives differing only by rotation about the Pt–N7 bond can vary by as much as 13 ppm (see Scheme 2).²² Sometimes even isotopomers are distinguishable: the ^{195}Pt isotope shift difference for Pt–³⁵Cl and Pt–³⁷Cl is 0.17 ppm and that for Pt–⁷⁹Br and Pt–⁸¹Br is 0.03 ppm.²³ Therefore in principle it is possible to count the number of Cl and Br ligands bonded directly to Pt via the isotope-splitting pattern. But in practice it is difficult to resolve such multiple patterns because of line broadening, which is due to either relaxation mechanism or temperature drift. The latter is a problem since the chemical shift of ^{195}Pt is strongly temperature-dependent (up to 1 ppm/K).

^{14}N NMR spectroscopy can be useful for ammine (–NH₃) and amine (–NH₂, –NH) groups which coordinate to Pt. Since ^{14}N is a quadrupolar nucleus (Table 2), and quadrupolar relaxation is dominant when the environment of ^{14}N has a low symmetry. This leads to broad resonances and subsequently reduces the sensitivity. However, the quadrupolar nature of ^{14}N has the beneficial effect of shortening the relaxation rate and allowing rapid pulsing so that a large number of transients can be acquired. It is still possible to follow reactions of cisplatin in blood plasma and cell-culture media at millimolar drug concentrations and to monitor ammine release.²⁴

^{15}N NMR is particularly useful in the study of the aqueous chemistry of cisplatin and other platinum ammine/amine compounds since ^{15}N -labeled compounds can readily be prepared. More importantly, both the ^{15}N NMR chemical shift (Figure 2) and the $^1J(^{15}\text{N}–^{195}\text{Pt})$ coupling constant are sensitive to the nature of the *trans*-ligand in Pt–NH₃ (or Pt–NH₂) complexes which provide useful information for identifying the ligands in the coordination spheres of Pt²⁺ (and Pt⁴⁺) (Figure 2). This technique has been used to characterize the reaction products of ^{15}N -labeled cisplatin.²⁵

The low receptivity of ^{15}N (3.85×10^{-6} relative to ^1H) limits its usefulness for directly detected ^{15}N -NMR studies of cisplatin and related platinum ammine/amine complexes in biofluids. The sensitivity of detection can be improved to some extent by ^{15}N isotopic enrichment and further enhanced

**Figure 2** Variation of ^1H and ^{15}N chemical shifts with the *trans*-ligand in Pt^{II}–NH, Pt^{II}–NH₂ and Pt^{II}–NH₃ complexes. (Adapted with permission from Ref.^{9b})

by polarization transfer from ^1H via for example, DEPT and INEPT experiments. But in practice, this enhancement of ^{15}N signal will be affected by the rate (k_{ex}) of exchange of protons between an ammine (and amine) and a solvent (e.g., water), and is hampered by rapid chemical exchange ($k_{\text{ex}} > J$). The maximum enhancement in ^{15}N signal via polarization transfer is only 9.8 (i.e., $\gamma_{1\text{H}}/\gamma_{15\text{N}}$). The repetition time of the pulse sequence is governed by the ^1H rather than the longer ^{15}N spin-lattice relaxation (T_1) which allows more rapid pulsing. $^{15}\text{N}\{^1\text{H}\}$ DEPT NMR techniques have been allowed the detection of rapidly changing intermediates in the reaction of ^{15}N labeled cisplatin with glutathione and also of ammine release following interaction of cisplatin with intracellular components of intact red blood cells at concentrations as low as 1 mM.²⁶ This method can be of values in situation where ^1H NMR resonances are very broad.

However, inverse ^{15}N methods ($^1\text{H}\{^{15}\text{N}\}$) are often preferred due to the greatly improved sensitivity for detection, by a theoretical maximum of 306 ($(\gamma_{1\text{H}}/\gamma_{15\text{N}})^{5/2}$) with respect to directly detected ^{15}N . This technique is based on the large one-bond $^1J(^{15}\text{N}–^1\text{H})$ coupling constant (ca. 70 Hz for $^{15}\text{NH}_3$) and it is necessary to work in H₂O (90% H₂O) since the NH protons normally exchange with deuterium rapidly in D₂O. The exchange of NH with solvent is much faster for Pt⁴⁺ than for Pt²⁺ complexes at neutral pH. Besides the high sensitivity, inverse detection also brings a simplification of complicated spectra since it selectively detects those protons directly attached to the labeled ^{15}N in the sample (e.g., Pt–NH₃), by use of the heteronuclear single (or multiple) quantum coherence transfer (HSQC or HMQC) pulse sequence. Each distinct type of Pt–NH resonance appears as a singlet, sometimes together with broadened ^{195}Pt satellites if ^{15}N decoupling is employed during the acquisition period (e.g., GARP method²⁷). Water suppression can be achieved by the use of pulse sequences incorporating pulsed field gradient (which can be employed for both coherence selection and suppression of water signal).²⁸

Figure 3 [^1H , ^{15}N] spectrum (left) of a 5 mM solution containing ^{15}N -cisplatin and its hydrolysis products in 95 : 5 = $\text{H}_2\text{O}/\text{D}_2\text{O}$ at pH 4.72, 300 K. ^{15}Pt satellites are marked on the 1D ^1H spectrum with an asterisk. Plots of the ^1H shifts of Pt-NH_3 vs. pH allow direct determination of the $\text{p}K_a$ values (right). (Adapted with permission from Ref.²⁹)

A one-dimensional ^1H spectrum (the first increment in a 2D experiment) contains only protons which are directly attached to the labeled ^{15}N in the sample ($\text{Pt-}^{15}\text{NH}$) and all others are eliminated. The combined detection of ^1H and ^{15}N in a reverse experiment, '2D [^1H , ^{15}N] HSQC NMR', is extremely powerful since the ^{15}N chemical shift range is large and diagnostic of the *trans*-ligand (Figure 2). The ^{15}Pt satellites in a 2D [^1H , ^{15}N] spectrum sometimes appears as diagonal peaks which correspond to the $^2J(^1\text{H-}^{15}\text{Pt})$ and $^1J(^{15}\text{N-}^{15}\text{Pt})$ coupling constants (again diagnostic) in the ^1H and ^{15}N dimensions, respectively (Figure 3) if they are not broadened beyond detection. The 2D [^1H , ^{15}N] method with ^{15}N -labeled platinum anticancer agents is particularly useful in studies of body fluids or cell culture media since thousands of overlapping ^1H resonances from other substances are filtered out. It takes just a few minutes to acquire a 2D [^1H , ^{15}N] spectrum at millimolar concentration and it is possible to detect ^{15}N -labeled species at concentrations as low as 20 μM .

2.2 Activation of Platinum Anticancer Drugs and Their Interaction with Nucleotides and DNA

It is widely accepted that the ultimate target for platinum anticancer drug is DNA and Pt-OH_2 bonds are much more reactive toward DNA and other biomolecules than Pt-Cl or Pt-OH bonds. The mechanism of action of cisplatin is believed to involve activation via hydrolysis inside cells where the concentration of chloride (Cl^-) (ca. 4 mM) is much lower than outside cells (ca. 104 mM). Therefore it is important to determine the rates of hydrolysis and $\text{p}K_a$ values of the

hydrolysis products. By the use of 2D [^1H , ^{15}N] HMQC spectroscopy, the $\text{p}K_a$ values can be rapidly measured at low concentration (Figure 3). By fitting the shift changes of ^1H NMR and ^{15}N -NMR as a function of pH, the $\text{p}K_a$ values of the monoaqua *cis*- $[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{H}_2\text{O})]^+$ (6.41) and diaqua adducts *cis*- $[\text{Pt}(\text{NH}_3)_2(\text{H}_2\text{O})_2]^{2+}$ (5.37 and 7.21) were determined.²⁹ The equilibrium constant for the first stage of cisplatin hydrolysis was also determined to be 2.72 based on the resonance integration of reacted cisplatin, and the mono- and di-aqua adducts. Since all hydrolysis products can be readily distinguished in the spectrum, the problems associated with other methods are overcome. The $\text{p}K_a$ values of aqua ligands of related platinum anticancer complexes such as *cis*- and *trans*- $[\text{Pt}(\text{NH}_3)(\text{cyclohexamine})\text{Cl}_2]$, and *cis*- $[\text{Pt}(\text{NH}_3)(2\text{-Pic})\text{Cl}_2]$ (2-Pic is 2-methyl-pyridine), have also been determined by this [^1H , ^{15}N] NMR method.^{30,31} The rate of hydrolysis for each chloride (Cl^-) ligand of *cis*- $[\text{Pt}(\text{NH}_3)(2\text{-Pic})\text{Cl}_2]$ was determined by the time-dependence of the [^1H , ^{15}N] NMR spectra for a period of over 20 h and was found to be slower than cisplatin.³¹

The reactions between ^{15}N -labeled cisplatin and guanosine-5'-monophosphate (5'-GMP) have also been investigated in aqueous solution by NMR spectroscopy.³² The short-lived reactive species *cis*- $[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{H}_2\text{O})]^+$ was detected during the early stages, followed by the formation of the mono- and bis-GMP adducts (Scheme 2). Hydrogen-bonding interactions were suggested to occur between N-H protons in Pt-NH_3 and deprotonated 5'-phosphate of GMP. Similar behavior was also observed between the N-H protons in ^{15}N -labeled ethylenediamine platinum complex $\{\text{Pt}(\text{en})\}^{2+}$ with GMP and adenosine monophosphate (AMP).³³

Figure 4 2D [^1H , ^{15}N] HSQC-NMR spectrum of 14-mer duplex d(ATACATG*G*TACATA)-d(TATGTACCATGTAT) after reaction with ^{15}N -cisplatin for 8 h. Labels: *, ^{15}N -cisplatin satellites; ‡, artefact. Peaks are assigned: 1, cisplatin; 2, $\text{cis-}[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{H}_2\text{O})]^+$; 3, $\text{cis-}[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{N}(7)\text{-G}(7))]^+$; 4, $\text{cis-}[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{N}(7)\text{-G}(8))]^+$; 5/6, $\text{cis-}[\text{Pt}(\text{NH}_3)_2\text{Cl}(\text{N}(7)\text{-G}(18/25))]^+$; 7,8, $\text{cis-}[\text{Pt}(\text{NH}_3)_2(\text{N}(7)\text{-G}(7))(\text{N}(7)\text{-G}(8))]^+$ (distorted and kinked forms). (Adapted with permission from Ref.³⁵)

The detailed kinetics for the interaction of cisplatin with 10- and 14-mer oligonucleotides have been investigated. The major species in the pathways of platination of mono- and bi-functional adducts (both single- and double-strand GG adducts) can be simultaneously detected in a single [^1H , ^{15}N] NMR experiment (Figure 4).^{34,35} The aqua-chloro intermediate which was usually present at micromolar concentrations, is readily monitored in these experiments and its lifetime was determined (ca. 8 min at 310 K) directly for the first time. Kinetic data obtained by [^1H , ^{15}N] NMR techniques are in close agreement with those determined by ^{195}Pt NMR spectroscopy (with enriched ^{195}Pt).¹⁴ However, no aqua-chloro intermediate was detected previously by ^{195}Pt NMR during the course of the reaction with DNA. As expected, the reactions of cisplatin proceed via an aqua-chloro intermediate, and lead to two monofunctional adducts on the duplex and two on the GG-containing single strand. One of the GG residues is platinated three-fold faster than the other, which is in line with the results obtained by HPLC,³⁶ and ring closure to form a GG chelate on the duplex (3'-G) occurs also faster by about an order of magnitude for one monofunctional adduct than the other. Surprisingly, the 5'-G monofunctional adduct on the duplex has a very long lifetime (over 5 days at 298 K).^{35,37} CD, ^1H and [^1H , ^{15}N] NMR

data have shown that the 14-base GG-platinated DNA duplex d(ATACATG*G*TACATA)-d(TATGTACCATGTAT) where G*G* is platinated guanine (at N7) by the $\text{cis-}[\text{Pt}(\text{NH}_3)_2]^{2+}$, undergoes a reversible pH-induced structural transition ($\text{p}K_a$ 4.8) between kinked-duplex and distorted forms. Binding of platinated duplex to the high-mobility-group protein 1 (HMG1) box A is at the concave face of the protein, and the kinked duplex may be converted to a different distorted form.³⁸ It is known that platinum forms bifunctional DNA adducts with the following order of sequence preference: $-\text{GG}- > -\text{AG}- \gg -\text{GA}-$ and that DNA platination is kinetically controlled. There is a clear preference for the formation of monofunctional adduct of cisplatin with $-\text{AG}-$ over the $-\text{GA}-$ sequence as judged from [^1H , ^{15}N] a HSQC NMR study. Closure to form the bifunctional adduct is more rapid in the former case than in the latter.³⁹ This could explain, at least in part, why $-\text{AG}-$ bifunctional adducts are preferentially formed and few platinated $-\text{GA}-$ adducts are observed.

2.3 Structures of Platinated Oligonucleotides

The anticancer activity of cisplatin and related complexes is believed to result from strong bonding of platinum to DNA affording mainly intrastrand $-\text{GG}-$ and $-\text{AG}-$ cross-links, the local structure of which are subsequently modified in such a way that apoptosis is induced.⁴⁰ The presence of these DNA cross-links in cisplatin-treated cancer patients correlates with positive responses to treatment with the drug.⁴¹ Such lesions have deleterious effects on DNA replication and transcription and cause mutations.^{42,43} Previous studies have shown that platinated-DNA was recognized by proteins containing one or more high-mobility-group (HMG) domains^{44–46} and structure-specific recognition protein 1.⁴⁷ The shielding of excision-repair caused by the binding of HMG proteins to DNA has been confirmed by both in vitro and in vivo experiments.^{48,49} Elucidation of the structural distortion of the cisplatin (and related complexes) DNA adduct at the molecular level is definitely an important step toward understanding the activity of platinum anticancer drugs.

Various techniques especially those of X-ray crystallography and NMR spectroscopy, can be utilized to study the structure of platinated DNA adducts, but NMR spectroscopy is the focus of this paper. ^1H NMR is particularly useful for studying DNA and almost all of the modern NMR techniques can be used. Additional information can be obtained from studies with other nuclei such as ^{13}C , ^{15}N , ^{31}P and ^{195}Pt . Platinated DNA structures were determined based on observed 1D and 2D NMR data (e.g., NOE) with the aid of molecular mechanics and dynamics calculations, and have been reviewed previously.⁵⁰

The structures of a number of platinated DNA adducts at either d(G*pG*) or d(A*pG*) sites have been solved and are listed in Table 3.^{51–60} Platinum cross-link induced structural distortion seems to be a common feature. The solution structure of the platinated octameric duplex d(CCTG*G*TCC)-d(GGACCAGG) shows that it is unwound by $\sim 21^\circ$, and kinked by $\sim 58^\circ$ toward the major groove at the d(G*pG*) site (Figure 5A). The minor groove is significantly widened and flattened at the platination site.⁵¹ The overall features are similar to those observed for the crystal structure of the platinated dodecameric duplex.⁶¹ The platinated duplex d(GCCG*G*ATCGC)-d(GCGATCCGGC) is also kinked by

~60° toward the major groove at the Pt²⁺ coordination site and unwound by 12–19°. ⁵² The solution structure of the platinated dodecamer duplex was reported recently. The *cis*-[Pt(NH₃)₂]²⁺-d(G*pG*) lesion causes the two adjacent –G*G*–bases to roll toward one another by 49°, leading to an overall helix kink by 78°. ⁵³ The helix deformation in solution is greater than that in crystal, and the structural differences may be attributable to crystal packing interactions. The structure of a AT-rich DNA 14-mer d(ATACATG*G*TACATA)·d(TATGTACCATGTAT) was determined and it was suggested that the bend of DNA induced by cisplatin is sequence dependent. ⁵⁴ Platination causes the overall DNA duplex to bend by ~52° toward the 3-end [with respect to the d(G*pG*) strand], in contrast to those GC-rich structures which bend toward the 5-end. The minor groove opposite the platination site is again widened and flattened. The solution structure of the d(G*pG*) platinated adduct of the nitroxide spin-labeled complex *cis*-[Pt(NH₃)(4-amino-TEMPO)]²⁺ (TEMPO = 2, 2, 6, 6-tetramethylpiperidinyloxy) with the undecamer duplex has been determined by using conventional NMR methods (e.g., NOE studies) and long-range (10–20 Å) proton–electron distance constraints. ⁵⁶ The use of long-range distance constraints did not affect the local geometry of the adduct only the global structure, but allows a better definition of the global structures of the duplexes. The platinated DNA duplex d(CTCA*G*CCTC)·d(GAGGCTGAG) cross-linked at the d(A*pG*) sequence by *cis*-[Pt(NH₃)₂]²⁺ also bends to the double helix towards the major groove in a way similar to that observed for the d(G*pG*) crosslink. ^{52,57} Molecular modeling based on published NMR and X-ray data suggested that all duplexes in the three-base-pair d(XpG*pG*) and d(XpA*pG*) region are very similar and protein binding does not greatly change the structure of this region. ⁶²

Interstrand d(G*pG*) crosslinks formed by cisplatin with oligomers have also been studied. ^{58,59} They occur predominantly between two guanines on opposite strands, which requires a distance of ca. 2.8 Å between the two N7 atoms. As for the intrastrand crosslink, the interstrand crosslink also causes a kink in the DNA helix. However, unlike the intrastrand crosslink, the kink and unwound is toward the minor groove. The deoxyribose of the platinated deoxyguanosine (G) is inverted so that O4' is pointing in the opposite direction to that of the remaining nucleotides. In addition, the complementary deoxycytidines (C), which were originally

Figure 5 NMR refined structures cisplatin-induced intrastrand (A) and interstrand cross-linked DNA duplex (B). The DNA is significantly altered from the B-form to accommodate cisplatin in (A), and the deoxycytosine residues originally base-paired to the platinated guanine have become extrahelical (B). Color code: C, green; H, metallic white; N, blue; O, red; P, orange; Pt, yellow. (Adapted with permission from Refs. ^{51,58})

base-paired to the platinated G are extruded and become extrahelical (Figure 5B). ⁵⁸ The localized change from B-DNA to a left-handed Z-DNA structure around the platination site was also observed. *Cis*-[Pt(NH₃)₂]²⁺ is also located in the minor groove of d(CCTCG*CTCTC)·d(GGAGCG*AGAG). The stacking of the two cross-linked guanines with the neighboring bases induces a kink of 40° toward the minor groove.

The 1,3-intrastrand d(G*XG*) (where X is C or T) cross-link minor adduct does not distort the global helical structure to the extent observed in the 1,2-intrastrand cross-link discussed above, but significantly disrupts local base-pairing and stacking at the 5'-end. The helix is bent by 24° and unwound by 19°. The platinum lesion causes a severe roll of 5'-G6 towards the major groove. ⁶⁰

2.4 Interaction with Amino Acids, Peptides and Proteins, and Their Metabolites in Biofluids

Increasing evidence has shown that platinum–peptide (amino acid and protein) interactions and particularly platinum–thioether interactions, play an important role in the mechanism of action of platinum drugs. The use of NMR

spectroscopy for studying these interactions has been summarized previously,⁹ and Pt–methionine complexes with various isomers have been characterized by ^{13}C , ^{15}N , and ^{195}Pt NMR. In fact, it has been shown that platinum species can initially bind to thioether groups and then migrate to N7 of guanine.^{63,64} ^1H and $[\text{}^1\text{H}, \text{}^{15}\text{N}]$ NMR spectroscopy has shown that L-methionine (Met) increases the rate of reaction of cisplatin with guanosine 5'-monophosphate (5'-GMP) at pH 7.⁶⁵ Therefore, methionines in peptides and proteins could play a role in the transfer of platinum onto DNA. Activation of carboplatin by reaction with L-Met derivatives could also provide an important pathway since carboplatin hydrolyses and interacts with chloride too slowly to account for its biological activity. Reaction with L-Met leads to a surprisingly stable ring-open intermediate with a half-life time 28 h at 310 K. By use of the 2D $[\text{}^1\text{H}, \text{}^{15}\text{N}]$ HSQC NMR method, a species with ^1H and ^{15}N shifts very similar to this intermediate was detected as a major metabolite in the urine samples from mice treated with ^{15}N -carboplatin.⁶⁶ This suggests that the ring-open intermediate is probably present in urine after carboplatin administration.

The thiolate-containing peptide glutathione (γ -L-Glu-L-Cys-Gly, GSH) is present in cells at mM concentrations. Various transient intermediates formed between the platinum complex and GSH during the reaction as judged by multinuclear NMR,^{9b,67} and a novel dinuclear platinum GSH complex was also isolated and its structure was proposed based on ESI-MS and various advanced 2D NMR techniques.⁶⁸ In contrast to thioethers, the binding of Pt^{2+} to thiolate tends to be irreversible and ammine/amine ligands will finally be released from initial complex. Reactions between cisplatin and intracellular thiols such as GSH may therefore inactivate the drug and moreover the Pt–GSH complex can be pumped out of the cisplatin-resistant cells.

There are conflicting reports on the role of Pt–protein adducts in the mechanism of action. On the one hand, it has been postulated that the binding of cisplatin to protein is probably the cause of many of the drug's side-effects, while on the other hand several reports suggest that Pt^{2+} -albumin adducts may be anticancer active. One day after intravenous infusion of cisplatin, 65–98% of the platinum in blood plasma is protein bound.^{69,70} Human serum albumin (66 kDa) is thought to be the major binding sites for cisplatin in human blood plasma. In contrast to previous reports, 1D and 2D $[\text{}^1\text{H}, \text{}^{15}\text{N}]$ NMR data suggest that ^{15}N -cisplatin mainly reacts with the methionine residues of albumin forming Met-S,N-macrochelates together with minor monodentates Met-S adduct and Cys34, the only free thiol of the protein.⁷¹ The iron binding protein transferrin (ca. 80 kDa) could deliver platinum to tumor cells, which are known to overexpress transferrin receptors. Diferric transferrin is taken up by cells via the known process of 'receptor-mediated endocytosis'. A combination of 2D $[\text{}^1\text{H}, \text{}^{13}\text{C}]$ and $[\text{}^1\text{H}, \text{}^{15}\text{N}]$ NMR spectroscopic studies using labeled transferrin (ϵ - $[\text{}^{13}\text{C}]$ Met labeled protein) and ^{15}N -cisplatin has shown that preferred Pt^{2+} binding site appears to be Met256 with an additional site at the surface-exposed methionine.⁷²

2.5 Other Metallo-anticancer Agents

Besides platinum, other metal complexes also have promising anticancer activity.^{2,3} Gallium nitrate is known to exhibit anticancer activity and is now being used clinically for the treatment of cancer-induced hypercalcemia. The octahedral Ru^{3+} complexes (low spin d^5) are more active against metastases than primary tumors, and may be prodrugs which are bio-reduced to Ru^{2+} species inside cells. Paramagnetically shifted ^1H NMR resonances are readily detected in ^1H spectra of Ru^{3+}

Figure 6 ^{71}Ga NMR spectra of ovotransferrin (1.3 mM, pH 7.6). (A) Before (bottom) and after addition of one (middle) and two mol equiv (top) of Ga^{3+} in the presence of 20 mM NaHCO_3 . (B) ^{71}Ga NMR spectra of Ga_2 -ovotransferrin (bottom), C-lobe of ovotransferrin (oTF/2C, 0.35 mM, 1.0 mol equiv of Ga^{3+}), and N-lobe of ovotransferrin (oTF/2N, 0.35 mM, 1.0 mol equiv. Of Ga^{3+}) in the presence of $\text{Na}_2\text{C}_2\text{O}_4$. (Adapted with permission from Ref.⁷⁵)

complexes and were used to determine the rate of hydrolysis of the anticancer agent *trans*-[RuCl₄(Im)₂][−] where Im is imidazole.⁷³ Interestingly, both Ru³⁺ and Ga³⁺ are thought to be delivered by human transferrin (hTF).^{2–4,74} It is known that many solid tumors express more transferrin receptor than normal cells. The binding properties of Ga³⁺ to ovotransferrin were investigated by ¹³C and ⁷¹Ga NMR. The latter technique is extremely useful at very high field once gallium has bound to large biomolecules.⁵ Ga³⁺ interacts preferentially with the N-lobe of the protein when carbonate is present as the synergistic anion, but enters equally both the N- and C-lobes of the protein when oxalate is the anion (Figure 6).⁷⁵ The binding of Ru³⁺ complexes to lactoferrin is at the imidazole of His253, one of the iron ligands in the iron binding cleft of the N-lobe, and is reversible with Ru release at pH 4–5 or in the presence of a large excess of citrate or adenosine triphosphate (ATP).

The organometallic titanocene and another Ti⁴⁺ complex have entered phase II and I clinical trials for anticancer, respectively. We have demonstrated by UV and various NMR spectroscopies that the Ti⁴⁺ complex binds strongly to human serum transferrin at the specific iron (Fe³⁺) site.⁷⁶ 2D [¹H, ¹³C] studies of ε-[¹³C]Met-hTF have shown that Ti⁴⁺ loads the C-lobe first followed by the N-lobe. Titanium (Ti⁴⁺) bound transferrin effectively blocked cell uptakes of ⁵⁹Fe-hTF into BeWo cells,⁷⁷ which indicated that titanium transferrin could be recognized by transferrin receptor and be taken up into cells.

3 GOLD ANTI-ARTHRITIC DRUGS

Several injectable Au⁺ thiolate drugs such as aurothiomalate and the oral drug auranofin are widely used for the treatment of difficult cases of rheumatoid arthritis and reviews on the medical use of gold have been published.^{78–80} The injectable Au⁺ complexes are polymers with thiolate sulfurs bridging to linear Au⁺, in chain or cyclic structures. The crystal structure of aurothiomalate has shown that linear S–Au–S units are arranged into polymeric double-helical structures.⁸¹ The structures of these polymers were found to be very sensitive to the ionic strength and pH of the solutions. Most of gold thiolate drugs often contain a small mol excess (10–15%) of thiol over gold.

One feature of these linear Au⁺ drugs is that they undergo facile thiolate exchange reactions and ¹³C NMR studies have shown that thiols with lowest pK_a values bind most strongly to Au⁺.⁸² The administered drugs are probably not the active species. Gold(I) is a soft metal and therefore has a very high affinity for soft ligands such as thiolate sulfurs, but binds only weakly to nitrogen and hardly at all to oxygen. Consequently proteins (and enzymes) containing thiolate groups (Cys residues) particularly those with low pK_a

values are targets for Au⁺. In blood, a major site for gold transport is Cys34 of serum albumin which has a low pK_a (~5). For the oral gold drug, ³¹P NMR has been extensively used to probe speciations in proteins, bio-fluids and cells.^{83–86} The ³¹P chemical shift of bound phosphine (Au–PEt₃, where Et is ethyl) is sensitive to the nature of the coordinated ligands (X) and release of PEt₃ can readily be detected. The PEt₃ (and thiomalate) ligands of auranofin (and aurothiomalate, AuStm) are initially retained on binding of gold to albumin:

Moreover, the ³¹P chemical shift of bound phosphine in RS–Au–PR₃ was found to correlate with the pK_a of thiolates (SR).^{82,86} ¹H and ³¹P NMR studies have shown that the rate of binding of gold drugs to albumin appears to be determined by the rate of opening of the cleft in which Cys34 is situated.^{87,88} Surprisingly, binding of auranofin and related gold compounds to Cys34 of albumin induces a structural transition, the effect of which can readily be observed by imidazole εCH¹H NMR resonances of His3 of the protein (Figure 7).^{88,89} Such communication between His3 and Cys34 may be explained by small changes in the arrangement of intervening helices 1 and 2 of domain I of the protein. This may be mediated by a *cis-trans* isomerization of Pro35, changing the environment of Cys34 from a buried to an exposed form. The structural change can also be induced by blocking Cys34 as a disulfide, e.g., cystine. Such a structural transition of albumin induced by gold drugs has even been detected in intact blood plasma by ¹H NMR spectroscopy.⁹⁰ The exposed position of bound gold may have important implications for the transport and bioavailability of gold–drug metabolites.

Cyanide appears to play an important role in the metabolism of gold drugs. It can readily replace the thiomalate ligand from aurothiomalate in vitro and Au(CN)₂[−] has been shown to be a metabolite of gold drugs in vivo.^{91,92} The enhanced uptake of gold into red blood cells of smokers is due to the formation of this species after inhalation of HCN in cigarette smoke. Interaction of aurothiomalate and cyanide (¹³C-enriched CN[−]) was followed by ¹H and ¹³C NMR spectroscopy.⁹² The mixed-ligand complex [(Stm)Au(CN)][−] (Stm=S-bound thiomalate) readily forms as an intermediate when [CN[−]]/[aurothiomalate] < 2, and Au(CN)₂[−] is the major species at higher ratio. Mixed-ligand complex of aurocyanide with other thiolate molecules such as glutathione, cysteine and captopril have also been reported.^{92–95} Thiols and cyanide both bind to Au⁺, although as expected, cyanide (CN[−]) binds more strongly. Under biological conditions where [thiols] ≫ [HCN], substantial displacement of cyanide may take place. This may facilitate the accumulation of gold by red cells where the intracellular glutathione concentration is high (mM). An aurocyanide complex of albumin was recently studied by ¹³C NMR spectroscopy and other techniques. There are two distinct binding mechanisms: the dominant mechanism is reversible association (non-specific binding) of intact Au(CN)₂[−] (δ_{13C} = 156.4) to albumin to form Alb-[Au(CN)₂]_n (δ_{13C} = 154.7, broad signal).⁹⁶ The second binding mechanism is at Cys34 to form Alb-Cys34Au(CN) via a ligand exchange reaction which accounts for only a minor fraction of the bound-gold (ca. 11%).

Figure 7 600 MHz ^1H spectrum of the aromatic region of a commercial sample of human albumin and fresh human blood plasma (A). The insert is $\text{H}\epsilon 1$ of His3 region of human blood plasma showing the n' to n switch after addition of gold drug. (B) is the model for structural changes induced by gold in domain I of albumin. (Adapted with permission from Ref.⁹⁰)

4 LITHIUM FOR MANIC DEPRESSION

Lithium is an element discovered over 177 years ago (1817), but it was not until the seminal work of the Australian scientist, John Cade 50 years ago,⁹⁷ and subsequent clinical studies by Mogens Schou, that lithium was seen by modern psychiatry as an effective treatment for manic depression. Both lithium carbonate and citrate compounds are widely used as a prophylactic treatment for bipolar disorders.⁹⁸ Doses are normally gram quantities and the therapeutic level of lithium in serum is about 0.4–1.2 mM, and clinical efficacy usually takes 1–2 weeks to become established. Previous studies have shown that lithium was widely distributed in the body following oral administration due to its high lability and its weakness towards complexation.

Despite intensive research, the biochemical basis for lithium's therapeutic effects still remains to be fully elucidated. Lithium ions are small but highly hydrated and could interfere with Mg^{2+} biochemistry due to their comparably high charge densities, the so-called 'diagonal relationship' between Li^+ and Mg^{2+} . However, the favored mode of action of lithium

is probably by interference with Ca^{2+} metabolism via inhibition of the inositol phosphate pathway.^{99–101} Lithium also stimulates glutamate release and protects neurons by inhibiting N-methyl-D-aspartate receptor-mediated calcium influx.^{102,103} Determination of lithium is normally made by spectroscopic methods, e.g., atomic absorption and nuclear magnetic resonance. The former involves the disruption of samples (e.g., cells) and ensuing tedious separation. In addition, the atomic absorption measurements are not specific to the intracellular compartments. By contrast, NMR provides a non-invasive and direct way to investigate lithium in cells and tissues.¹⁰⁴

Naturally occurring lithium consists of two isotopes ^6Li and ^7Li , with natural abundance 7.42 and 92.58%, respectively (Table 2). Both isotopes are weakly quadrupolar and the quadrupole moment of ^6Li is the smallest known while that of ^7Li is amongst the smallest, and they both give narrow resonance lines and have long spin-lattice relaxation times (T_1).¹⁰⁵ However, ^7Li is the choice for most biological studies because of its high sensitivity, higher natural abundance and more favorable relaxation as compared with ^6Li . The chemical shift range of ^7Li is small (ca. 15 ppm) due to its simple electronic structure and aqueous chemistry. The NMR spectrum of ^7Li generally contains a single peak corresponding to the overlapping signals from different environments, e.g., intra- and extra-cellular. It is possible to differentiate ^7Li signals from different compartments, for example, ions within the cells and those that are free in the extracellular bathing fluid, based either on their different relaxation properties or with the aid of shift reagent (e.g., dysprosium tripolyphosphate), Figure 8.¹⁰⁶ Shift reagents, which are negatively charged lanthanide complexes and are insoluble in hydrophobic cell membrane, are repelled by the negatively charged head groups of phospholipids at the surface of cell membranes. In contrast to other alkali metals, ^7Li ($I = 2/3$) actually resembles a spin 1/2 nucleus and relaxation tends to be dominated by the dipolar mechanism.

The application of ^7Li and NMR of other alkali-metals to study the interaction of these metal ions with metalloproteins have been reviewed.¹⁰⁷ The chemical shifts of ^6Li , ^7Li and other alkali metal ions except Cs^+ , are normally insensitive to either solvation or complexation by biomolecules. Li binds to myo-inositol monophosphatase, an enzyme that is inhibited by lithium and is thought to be the primary target for lithium therapy, and induces a downfield shift by <0.1 ppm and broadening of the ^7Li NMR signal. The binding constant at a single site was calculated to have a K_d of 1 mM, and lithium was found to compete with group II metal ions such as Mg^{2+} at that site.¹⁰⁸ NMR investigation of Li^+ binding to phospholipids and cell membrane have also been reported.

In order to get into the brain where the site of action of lithium is, Li^+ must be absorbed through the gastrointestinal tract into blood and pass the blood brain barrier. Clearly the membrane transport of lithium is a critical feature and several different NMR techniques have been used depending on the time-scale of the lithium transport process. The best model available for the study of Li^+ transport in human cells is the erythrocyte, which is also believed to be a good model for the blood brain barrier. Numerous NMR studies of Li^+ transport and environment in erythrocytes have been reported.^{109,110} Depressed patients with a high $[\text{Li}]_i/[\text{Li}]_e$ ratio, where 'i' and 'e' represent intra- and extra-cellular concentration of lithium, were found to have a better therapeutic response that

Figure 8 ^7Li NMR spectra of rat blood samples with added shift reagents (dysprosium tripolyphosphate, $\text{Dy}(\text{ppp})_2^{7-}$). The peaks at 0 and ca. -10 ppm correspond to intracellular and extracellular ^7Li , respectively. The various doses of LiCl administered to the rats are indicated next to each spectrum. (Adapted with permission from Ref.^{110b})

those patients with a lower ratio.¹⁰⁹ It was suggested that erythrocyte Li concentration could serve as a useful indicator of clinical response. However, subsequent studies were unable to substantiate the initial findings, and it is now generally accepted that this parameter is not clinically useful partly due to large interindividual variations in ionic transport process. It is known that a considerable amount of Li^+ enters the erythrocytes with the $[\text{Li}]_i/[\text{Li}]_e$ ratio typically at 0.3–0.6 which indicated that Li is actively extruded from the cells. Higher ratios have been reported recently in the low dose range in rats (Figure 8) and the coadministered drug, thioridazine, has no effect on erythrocytes and plasma lithium levels.^{110b,c}

In spite of extensive investigations of erythrocytes, little is known about the transport behavior of Li^+ in other cells and major differences are expected between erythrocytes and the excitable, nucleated cells of the central nervous system such as neurons and glia. Li^+ transport processes and intracellular concentrations in the brain have been approached by using human nerve 1321 N1 astrocytoma. ^7Li NMR spectroscopy showed that the uptake of Li^+ was approximately ten times faster than that into human erythrocytes and the steady-state was reached within 60 min. The low intracellular Li^+ concentration ($[\text{Li}]_i/[\text{Li}]_e \sim 0.3$) suggested the presence of an efflux mechanism in astrocytomas. Similar results have been obtained very recently for cultured human neuroblastoma SH-SY5Y cells.^{112,113} Intra- and extra-cellular ^7Li resonances could be resolved in the presence of the shift reagent and relaxation measurements showed that Li^+ is immobilized more in human SH-SY5Y cells than in human erythrocytes.

Significant increases in the first-order rate constants for Li^+ influx and efflux in the presence of veratridine (0.05 mM) suggested the Li^+ transport was mediated via Na^+ channels, a pathway not present in erythrocytes.¹¹³ The studies of cultured central-nerve-system cells will also provide important information for in vivo study.

Direct investigation of Li^+ in the brain may be a better measure of efficacy or neurotoxicity than that in the serum. The spatial distribution of Li in the brain may also shed light on the still unknown mechanism of action of Li. Due to its relatively high sensitivity, the sufficiently high enough concentration of Li in tissues and most importantly the development of NMR spectroscopy in vivo, ^7Li NMR has successfully been used in recent years as a new tool to measure brain tissue lithium concentration.^{104,114–117} Renshaw and coworkers' pioneering work demonstrated the feasibility of in vivo tissue measurements of lithium in animal and in human subjects.^{118,119} In animals, efforts have been made to develop methods for measuring the pharmacokinetics of uptake in brain. It was found that the time constant for the uptake of a single dose of Li in rat brain was 48–98 min with signals that were uncontaminated by those from surrounding tissues.¹²⁰ Because of the high dose and long acquisition times used, the distribution of Li in the rat brain could be determined by ^7Li NMR imaging although the resolution of these imaging is overall quite poor.^{121,122}

Most recent ^7Li work in vivo has focused on humans. Initial unlocalized studies measured the kinetics of uptake and elimination of ^7Li and compared serum and brain concentrations. Several studies have confirmed that the concentration of Li in brain is typically 0.1–0.6 mM and indicated brain/serum ratios of 0.4–0.7. Preliminary studies have attempted to examine a possible relationship between brain Li levels and therapeutic response, suggesting that Li brain levels may be of clinical relevance.^{123–125} However, this question has yet to be properly addressed in patient samples large enough to provide a more clear answer. The potential for ^7Li in vivo NMR as an important tool for investigation of Li^+ refractoriness and predication of treatment outcome in bipolar disorder patients is currently being investigated.^{116,126}

5 BISMUTH ANTIULCER (AND ANTIMONY ANTILEISHMANIA) AGENTS

Arsenic, antimony and bismuth have long been associated with medicine. Currently antimony compounds are used clinically for the treatment of leishmaniasis and bismuth compounds are widely used as antiulcer drugs (Table 1). Recently clinical studies in China demonstrated that the classical inorganic compound, arsenic trioxide (As_2O_3) can induce remission in patients with acute promyelocytic leukemia (APL, a rare blood cancer).^{127,128} The induction of apoptosis and partial differentiation may be responsible for the activity of this metal.¹²⁹ Progress in the understanding the mode of action and design of drugs based on these elements are being greatly held up through lack of a suitable probe for the metal itself. NMR studies of these complexes have therefore relied on the observation of ligand nuclei such as ^1H and ^{13}C . The binding of citrate to Bi^{3+} in antiulcer complexes has been studied by ^1H , ^{13}C and $[^1\text{H}, ^{13}\text{C}]$ NMR spectroscopy.^{130–132} Citrate is a good bridging ligand and polymeric species are

formed in solution. The structures of bismuth citrate complexes are complicated, being dependent on pH, concentration, [Bi : citrate] ratio and the counter cations present. Different bismuth citrate species are in fast exchange on the NMR time-scale at pH < 6.2; the exchange rate decreases at pH > 6.2, and different species can be observed.^{130,131} By means of diffusion-ordered 2D [¹H, ¹³C] HSQC NMR spectroscopy together with isotope-labelling of citrate (¹³C₂/¹³C₄), a wide range of different types of bound citrate can readily be detected at low Bi concentrations (5 mM) in aqueous solutions of ranitidine bismuth citrate at pH* 7.4. There appears to be an equilibrium between free citrate, dinuclear species [Bi(citrate)₂Bi]²⁻ and multinuclear bismuth citrate clusters at physiological pH values. The solid-state structure of the anti-ulcer drug, ranitidine bismuth citrate may be closely related to that of Na₂[Bi₂(citrate)₂·7H₂O] in view of the similarity in their chemical compositions (Bi : citrate = 1 : 1), crystallization conditions (ca. pH 4), and solid-state ¹³C NMR spectra.¹³³ Second coordination sphere interactions between coordinated citrate and ranitidine have been detected by ¹H NMR.¹³⁰

Both antimony and bismuth form stable complexes with the tripeptide glutathione (GSH) with a stoichiometry [Bi(GS)₃] or [Sb(GS)₃]. The rate of uptake of these metals into red blood cells and complexation with intracellular glutathione as determined by spin-echo ¹H NMR, is rapid for Sb³⁺ (minutes) and relatively slow for Bi³⁺ (hours).^{134,135} Strong binding of Sb³⁺ to trypanothione [T(SH)₂] was chemically characterized for the first time by ESI-MS spectrometry and NMR spectroscopy. In contrast to the glutathione complex, each Sb³⁺ coordinates to only one T(SH)₂ with two sulfurs being provided from Cys residues and probably an oxygen from water.¹³⁶

Binding of bismuth to human transferrin was unexpectedly strong.^{137,138} The uptake of Bi³⁺ by apo-transferrin from bismuth citrate complexes is very slow (hours at 310 K) and occurs in at least two steps, whereas transfer from bismuth nitrilotriacetate is rapid (min). ¹³C NMR suggests that bismuth binds to transferrin along with carbonate (CO₃²⁻) as the synergistic anion, which is similar to Fe³⁺. Binding of Bi³⁺ occurs preferentially to the C-lobe of transferrin. This order of lobe-loading has been confirmed by 2D [¹H, ¹³C] heteronuclear multiple-quantum coherence (HMQC) NMR studies using recombinant ε-[¹³C]Met-hTF (ca. 0.3 mM) in which all Met residues are enriched with ¹³C at the -SCH₃ group. The changes in shift of the ¹H and ¹³C NMR resonances of Met can be used not only as a probe for determining the order of lobe-loading of transferrin with metal ions, but also as fingerprints of conformational changes induced by Bi³⁺ and other metal ions. Bi³⁺, Fe³⁺, Ga³⁺ and Al³⁺ probably induce similar conformational changes in hTF, since the changes in shifts of SCH₃ resonances (Met) are almost identical.¹³⁹ Due to the ¹³C labeling of Met and the sensitivity enhancement obtainable by inverse detection, the possible metal binding (e.g., Bi³⁺) to transferrin (ε-[¹³C]Met-hTF) can readily be detected in the presence of large excess of other proteins and even in blood plasma by 1D and 2D [¹H, ¹³C] NMR spectroscopy.¹⁴⁰ Transferrin was found to be a potential mediator for Bi³⁺ transport in blood plasma, which may have implications for the mechanism of neurotoxicity of Bi³⁺ drugs.

6 SUMMARY

NMR spectroscopy is one of the most powerful techniques for the study of interactions of metallodrugs with molecules of biological importance. The chemical shifts of some nuclei such as ¹⁹⁵Pt are sensitive to either the oxidation state or to coordination sphere and provide information on the binding site of the metallodrug-biomolecule complex. With the development of NMR techniques and currently available high-fields (e.g., >17 T), more information is expected to be obtained from NMR experiments. The recent success of ⁶⁷Zn NMR in the study of a metalloprotein may shed light on other biologically relevant quadrupolar nuclei.¹⁴¹ The use of inverse detection of ¹³C or ¹⁵N (e.g., 2D HSQC, HSQC-TOCSY, HSQC-NOESY) together with isotopically-labeled metallodrugs or biomolecules, allows studies to be conducted at physiologically relevant concentrations. The structures and dynamics of metallodrug-biomolecule complexes which have been investigated by 1D and 2D homo- and hetero-nuclear NMR techniques will continue to be an important field of study. Theoretically, drug discovery of inorganic compounds can also be screened based on structure-and-activity relationship NMR (SAR-NMR)¹⁴² and we have demonstrated that metallodrug binding to the 80 kDa protein (transferrin) can readily be followed.^{139,140} Screening the binding of inorganic compounds to larger proteins and enzymes should now be possible by the transverse relaxation-optimized spectroscopy (TROSY) experiment.¹⁴³ The combination of NMR techniques with chromatography (LC-NMR and HPLC-NMR) should be a powerful method for the identification of novel metallodrug metabolites.¹⁴⁴

1 INTRODUCTION

The central idea of the pioneers of this general research was to find a molecule¹ which was nonreactive and particularly sensitive to its environment, physical interactions with other chemical species, and the nature of adsorption sites, which could be used as a probe for determining in a new way solid properties that are difficult to detect by classical physicochemical techniques. In addition, the probe needed to be detectable by NMR spectroscopy, since this technique is particularly suitable for investigating electron perturbations in rapidly moving molecules.

Xenon is this ideal probe because it is an inert gas, is monoatomic, and has a large spherical electron cloud. From the NMR point of view, the ^{129}Xe isotope has a spin of $\frac{1}{2}$, its natural abundance in xenon is 26%, and its sensitivity of detection relative to the proton is about 10^{-2} . The recent development by Pines and co-workers of xenon optical polarization techniques offers increased sensitivity by a factor of 10^3 for the detection of adsorbed xenon.^{2,3} The high polarizability of the xenon atom makes it very sensitive to its environment. Small variations in the physical interactions with the environment cause marked perturbations of the electron cloud; these are transmitted directly to the xenon nucleus and greatly affect the NMR chemical shift.

2 CHEMICAL SHIFT OF XENON ADSORBED ON A ZEOLITE

In pure xenon gas,⁴ the ^{129}Xe chemical shift can be expressed by a virial expansion of the xenon density ρ :

$$\delta(T, \rho) = \delta_0 + \delta_{1,\text{Xe}}(T) \cdot \rho_{\text{Xe}} + \delta_{2,\text{Xe}}(T) \cdot \rho_{\text{Xe}}^2 + \delta_{3,\text{Xe}}(T) \cdot \rho_{\text{Xe}}^3 + \dots \quad (1)$$

where $\delta(T, \rho)$ is the resonance shift at temperature T and density ρ . The term δ_0 is the value of the resonance shift extrapolated to an infinitely low density; $\delta_{i,\text{Xe}}(T)$ are the virial coefficients of the shift in density.

For mixtures of xenon and another gas A, Jameson et al.⁴ showed that, in the linear range,

$$\delta = \delta_0 + \delta_{1,\text{Xe}}(T) \cdot \rho_{\text{Xe}} + \delta_{1,\text{A}}(T) \cdot \rho_{\text{A}} \quad (2)$$

where ρ_{Xe} and ρ_{A} are the densities of xenon and 'solvent' molecules A, respectively; $\delta_{1,\text{Xe}}$ and $\delta_{1,\text{A}}$ characterize the Xe–Xe and Xe–A interactions, respectively.

As in the gas phase, most information has been obtained from analyzing the variation in the chemical shift with xenon concentration, generally at 26 °C. The amount of xenon adsorbed is expressed as the number of atoms N per gram of anhydrous zeolite or the number of atoms n_s per cage (zeolites Y, ZK-4, erionite, etc.).

Fraissard et al. have shown that the chemical shift of adsorbed xenon is the sum of several terms corresponding to the various perturbations that it experiences^{1,5,6}

$$\delta = \delta_{\text{ref}} + \delta_s + \delta_{\text{Xe}} + \delta_{\text{SAS}} + \delta_{\text{E}} + \delta_{\text{M}} \quad (3)$$

δ_{ref} is the reference (gaseous xenon at zero pressure). The term δ_s accounts for interactions between xenon and the surface of the zeolitic pores, assuming that the solid does not contain any electrical charge; thus it depends only on the dimensions of the cages or channels and on the ease of xenon diffusion. The term $\delta_{\text{Xe}} = \delta_{\text{Xe-Xe}} \cdot \rho_{\text{Xe}}$ accounts for Xe–Xe interactions; it increases with increasing local density of adsorbed xenon and becomes predominant at high xenon pressure. When the Xe–Xe collisions are isotropically distributed (large spherical cage) the relationship $\delta = f(N)$ is a straight line (Figure 1, curve 1). The slope, $d\delta/dn$ is proportional to the local xenon density and, therefore, inversely proportional to the 'void volume'. If the Xe–Xe collisions are anisotropically distributed (narrow channels), $d\delta/dN$ increases with N (Figure 1, curve 2).

When there are strong adsorption sites (SASs) in the void space, these interact with xenon much more than do the cage or channel walls, and each xenon atom spends a relatively long time on the SAS, particularly at low xenon concentration. The corresponding chemical shift δ_{SAS} will be greater than in the case of a noncharged structure (Figure 1, curve 3). When N increases, δ must decrease if there is fast exchange of the atoms adsorbed on the SASs with those adsorbed on other sites. When N is high enough, the effect of Xe–Xe interactions again becomes the most important factor, and the dependence of δ on N is then similar to that shown by curve 1 in Figure 1. In this case, $\delta_{N \rightarrow 0}$, (the chemical shift extrapolated to zero concentration) depends on the nature and number of these SASs. Often, these SASs are charged, and sometimes they are paramagnetic cations. The theoretical curve (3 in Figure 1), is displaced to high frequency (Figure 1, curve 4). The difference between curves 1 and 3 shows the effect (δ_{E}) of the electrical field and, if present, the effect (δ_{M}) due to the magnetic field created by these cations.¹

Figure 1 Variation in the chemical shift of xenon adsorbed on a porous solid. See text for details

3 INFLUENCE OF THE PORE STRUCTURE ON Δ_s : APPLICATION TO POROSITY

The relationship $\delta = f(N)$ is characteristic of the zeolite structure when the Si/Al ratio is very high and when there are no strong adsorption sites accessible to xenon. Figure 2 illustrates the sensitivity of this technique to the pore structure. The slopes of the curves depend on the void volume of the pores; this is logical because for a given number of xenon atoms per gram, the local density and thus the Xe–Xe interactions depend on this volume. The chemical shift δ_s at zero concentration is related to the structure; the smaller the channels or cavities, or the more restricted the diffusion, and the greater δ_s becomes.

It is assumed that at 26 °C the experimental chemical shift is the average of the shift of xenon in rapid exchange between a position A on the pore surface (denoted by δ_a) and a position in the volume V of the cavity or channel (denoted by $\langle\delta_v\rangle$):

$$\delta = \frac{N_a\delta_a + N_v\langle\delta_v\rangle}{N_a + N_v} \quad (4)$$

where N_a and N_v are the number of xenon atoms in each state. This equation is valid for any xenon concentration, and thus for $N \rightarrow 0$, $\delta \rightarrow \delta_s$.

$\langle\delta_v\rangle$ is a function of δ_a and the distance traveled by the xenon atom between two successive collisions with the pore wall. In fact, $\delta_v = \delta_a$ when the xenon leaves the surface. δ_v then decreases during the journey between two collisions, and thus the need to determine the mean value $\langle\delta_v\rangle$.

In order to obtain by ^{129}Xe NMR precise data on the void space of a zeolite of unknown structure and the dimensions

Figure 2 Chemical shift δ of adsorbed ^{129}Xe versus the number of xenon atoms per gram of solid

of structural defects, Springuel-Huet et al.⁷ have calculated the ‘mean free path’ $\bar{l}$ of xenon imposed by the structure, and determined the dependence of δ_s on $\bar{l}$, both experimentally and by calculation (sphere, infinite cylinder):

$$\delta_s = \delta_a \frac{a}{a + \bar{l}} \quad (5)$$

where a is a constant. Equation (5) can be deduced from equation (4).⁸ The large variation in δ_s with $\bar{l}$ (Figure 3) proves that ^{129}Xe NMR is very sensitive to pore dimensions.

Derouane and Nagy have been able to relate δ_a to the curvature of the adsorbing surface and, therefore, also to the pore diameter.⁵ Finally, Ripmeester et al.⁸ have continued this study by calculating the Lennard–Jones potential curves for a xenon atom and a spherical layer representing the atoms of a cage. They deduced that in small cages xenon is ‘solid like’ and in larger cages ‘gas like’, and that consequently it is difficult to imagine a single correlation between the xenon chemical shift and the dimensions of the adsorption zones.⁸

The symmetry of the adsorption site can sometimes be reflected by the form of the signal when the interactions to which the xenon atom is subjected are highly anisotropic. For example, Springuel-Huet and Fraissard have shown that the ellipsoid-shaped channels of SAPO-11 and AlPO₄-11 cause chemical shift anisotropy effects to be observed in the ^{129}Xe NMR spectra of adsorbed xenon,^{3,5} due to the similarity between the small axis of the pore section (0.67×0.39 nm) and the diameter of the xenon atom (0.44 nm). Similar results have been obtained by Ripmeester et al. on Xe/clathrates systems.³

Figure 3 Variation in δ_s versus the mean free path l . F, ferrierite; Z-5, ZSM-5; Z-12, ZSM-12; Z-48, ZSM-48; A-5, AIPO₄-5; A-11, AIPO₄-11; A-17, AIPO₄-17; S-34, SAPO-34; S-37, SAPO-37

When the zeolite structure includes several adsorption zones, the xenon spectrum must contain an equal number of components characteristic of these zones, provided that the diffusion of the xenon atoms is not too rapid on the NMR timescale.¹ Thus, the spectrum of sodium mordenite shows two signals at 26 °C, arising from xenon in the main channels and in the side pockets.^{1,3,5} However, because of rapid exchange of xenon between these two regions there is only one signal for H⁺-exchanged mordenite. The spectrum of ferrierite at 26 °C shows two signals characteristic of two types of channel.^{3,5} In this case it was even possible to detect the presence of a mordenite intergrowth. Two signals have also been detected for the Xe/H-Rho system, but only at a temperature as low as −50 °C so as to avoid rapid exchange of atoms located in the octagonal prisms and the large cavities. In Cs-Rho, only the signal corresponding to the large cavities is detected, since all the prisms are occupied by Cs⁺.^{5,6}

It is clear from these examples that this ¹²⁹Xe NMR can be used to identify all the different microporous adsorption zones, namely the structure defects in zeolites,¹ heteropolyanions, solid polymers,³ clathrates,^{3,6} etc.

4 INFLUENCE OF TEMPERATURE

The study of the temperature dependence is another way of checking the size of the pores in which the xenon is adsorbed.⁹ The variation in temperature changes the relative residence times of xenon on the surface and in the free space, which in turn influence the xenon chemical shift. The variation in δ thus depends on $\langle\delta_v\rangle$. The variation is very small if $\langle\delta_v\rangle \simeq \delta_a$ (ZSM-5), and very large if $\langle\delta_v\rangle \ll \delta_a$ (Na-Y) (Figure 4).

Figure 4 Variation in δ_s versus the temperature T of the experiment

From a quantitative point of view, Chen and Fraissard⁹ have shown that

$$d \left(\ln \frac{\delta_a - \delta_s}{\delta_s - \langle\delta_v\rangle} \right) / dT = - \frac{\Delta E}{RT^2} \quad (6)$$

where ΔE is the energy difference between the xenon in the two states A and V. The fast exchange model is valid in the temperature range where the plot of $\ln [\delta_a - \delta_s / \delta_s - \langle\delta_v\rangle] = f(1/T)$ is a straight line.

5 EFFECT OF THE Si/Al RATIO OF ZEOLITES

The relationship between δ_s and the porous structure is strictly valid only for an electrically neutral surface. The chemical shift of xenon must therefore depend on the chemical composition of the zeolite, in particular on the number of charges, i.e. on the Si/Al ratio. This dependence is more pronounced when the temperature is low and the pore diameter is small (increased effect of δ_a with the contact time of xenon at the surface).

In the case of faujasite, either with Na⁺ or decationized, the $\delta = f(N)$ relationships are almost parallel straight lines at 26 °C, and $\delta_{N \rightarrow 0}$ decreases monotonically by 4 ppm when Si/Al increases from 1.28 to 54.¹ For ZSM-5 and ZSM-11 (narrow channels) the dependence of $\delta_{N \rightarrow 0}$ on the aluminum concentration is greater than for faujasite (large cavities). In addition, this variation shows a break at about [Al] = 2 Al atoms per unit cell, which demonstrates that the xenon–wall interactions change at this concentration.¹⁰ Thus aluminum is not randomly distributed in the lattice; rather, its distribution depends on the concentration. Finally, we mention the difference between the $\delta = f(N)$ relationships for ZSM-5 and ZSM-11 for [Al] ≥ 2 Al atoms per unit cell. Despite the similarity of the structures of these two zeolites, the sensitivity

of the ^{129}Xe NMR technique is sufficient to differentiate between them.

6 INFLUENCE OF CATIONS

It has been explained in Section 2 why the $\delta = f(N)$ curve goes through a minimum when there are strong adsorption sites in the zeolite. This has been shown for X and Y zeolites with divalent cations such as Mg^{2+} , Ca^{2+} , Zn^{2+} , Cd^{2+} , and Ni^{2+} ,^{1,6,11} where xenon adsorption becomes saturated within the given pressure range.

Using a fast exchange model analogous to the one proposed by Springuel-Huet et al.,⁷ but taking into account the possible presence of SASSs, Cheung et al. were able to give an analytical expression of these curves in the form:¹²

$$\delta = \frac{\alpha}{\rho} + \delta_g \cdot \rho \quad (7)$$

where ρ is the overall xenon density in the zeolite, δ_g is the $\delta_{1,\text{Xe}}$ coefficient [as in equation (1)], and α depends on the distribution of N_a and N_v [as defined in equation (4)]. The $1/\rho$ dependence results in an initial decrease in δ with increasing surface coverage, before the term linear in ρ begins to dominate. Let us consider, for example, $\text{Mg}_\lambda\text{-Y}$ and $\text{Ca}_\lambda\text{-Y}$ zeolites, dehydrated under vacuum at 500°C , where λ denotes the degree of cation exchange with Na^+ .¹ When Ca^{2+} cations are in the sodalite cage or the hexagonal prisms ($\lambda < 55\%$), δ is a linear function of the xenon concentration (as for Na-Y), regardless of the extent of dehydration of the sample. When some Ca^{2+} cations are situated within the supercages ($\lambda > 55\%$), for $\text{Ca}_\lambda\text{-Y}$ one observes values of δ (compared with Na-Y) that are greatest when λ is high, especially at low xenon concentration. According to Ito et al., the experimental value of $\delta_{N \rightarrow 0}$ for $N = 0$ is roughly proportional to the square of the electric field at the nuclei of xenon atoms adsorbed on Ca^{2+} cations.¹

According to Cheung et al., the high value of δ is not due solely to the high degree of polarization of xenon and the distortion of the xenon electron cloud by the strong electric fields created by the divalent cations. They suggest the formation of a partial bond between these two species formed by the donation of a xenon 5p electron to the empty s orbital of the divalent cation.¹² A similar model concerning electron transfer from xenon to platinum was proposed by Ito et al. to explain the large shift in δ for platinum supported on Na-Y.¹

The effect of the dehydration and rehydration of zeolites on the influence of Ca^{2+} cations can also be studied by ^{129}Xe NMR.¹ For example, the chemical shift δ and the signal width $\Delta\omega$ of xenon adsorbed on $\text{Mg}_{70}\text{-Y}$ increase with increasing dehydration of the solid. The values of δ and $\Delta\omega$ are greatest when dehydration is complete. Conversely, the spectra evolve with rehydration: for a given xenon pressure, line *a* due to xenon in the supercages containing only bare Mg^{2+} decreases in favor of line *b* corresponding to Mg^{2+} surrounded by water molecules. ^{129}Xe NMR therefore makes it possible to follow the diffusion of an adsorbate in a zeolite crystallite.

The problem is more difficult in the case of paramagnetic cations, especially when the extent of exchange is so high that the magnetic term [δ_M in equation (3)] becomes large. However, Scharf et al. have succeeded, using this technique,

in following the reduction and reoxidation of the $\text{Ni}_{7.5}\text{-Na-Y}$ zeolite desorbed under vacuum at 350°C .^{1,6} When the sample was reduced at lower temperatures (about 100°C) two types of environment for the xenon atoms were evident: one corresponding to xenon in the nickel-exchanged material, and the other corresponding to xenon in contact with Na-Y or H-Y. Reduction at higher temperatures produced a low-frequency shift of the first resonance, indicating that this environment becomes more like the environment of xenon in the Na-Y zeolite. At the highest temperature (370°C) studied, only the line corresponding to xenon in Na-Y was detected. These results prove that nickel ions are removed from the supercages upon reduction. Using this method, Scharf et al. showed that reoxidation under 80 kPa of oxygen at various temperatures does not reverse the process of reduction.

A particularly interesting case is that of faujasite-type zeolites containing Ag^+ or Cu^+ cations, the external electron structure of which is *nd*.¹¹ The ^{129}Xe NMR isotropic chemical shifts of xenon in Na-X and in the fully silver-exchanged zeolite Ag-X are shown in Figure 5. The shifts in dehydrated and oxidized Ag-X are distinctly lower than that for Na-X over the range of concentration studied. Most remarkably, the shifts decrease with concentration, down to negative values in the range -40 to -50 ppm at low xenon concentration. In contrast to these results, the samples reduced at 100°C and 300°C show high-frequency shifts with respect to Na-X. After reduction at 100°C , δ increases steadily with the number of xenon atoms per supercage (n_s) from $+100$ ppm to about $+170$ ppm for about $0.3 < n_s < 4$, whereas after reduction at 300°C the shift values are between $+140$ and $+160$ ppm for $0.1 < n_s < 1$, with a shallow minimum at about $n_s = 0.7$. In the latter case, the plot of $\delta = f(N)$ has the classical shape of zeolite-supported metals. The very unusual low-frequency shift in the case of the dehydrated and oxidized samples is due to a specific interaction of xenon with Ag^+ cations in the supercages. This shielding is due to $d_\pi\text{-}d_\pi$ back-donation from silver to xenon, involving the silver 4d and the xenon 5d orbitals.

Similar studies have confirmed that Cu^{2+} is autoreduced to Cu^+ during the dehydration of Cu-Y at 400°C , and it has been

Figure 5 ^{129}Xe NMR chemical shift versus the number of xenon atoms per supercage (n_s) for the zeolites: Na-X (400 dehydrated, ●); Ag-X (400 dehydrated, ■); Ag-X (450 oxidized, ▽); Ag-X (100 reduced ×); Ag-X (300 reduced, ▲)

shown that there are only Cu^+ ions in the supercages.¹¹ The Cu^{2+} cations are located in the sodalite cavities or the prisms.

7 CATION EXCHANGE BETWEEN DIFFERENT ZEOLITES

^{129}Xe NMR of adsorbed xenon can be used to follow the exchange of cation sites in the zones accessible to xenon in a given crystallite, and to visualize the exchange of cations between different zeolites. For example, the two peaks in Figure 6(a) at 144 and 89 ppm correspond to xenon adsorbed in dehydrated RbNa-X and Na-Y zeolites, respectively.¹³ Upon mechanical mixing at 300 K [Figure 6(b)] the intensities of the two signals decrease and a third broad signal at about 141 ppm appears. After further treatment of the mixture at 673 K and 0.01 Pa [Figure 6(c)], there is a further larger decrease in the intensities of the RbNa-X and Na-Y signals, the peak at 141 ppm disappears and two additional broad signals are seen at 128 and 109 ppm.

The two xenon resonance signals corresponding to the two pure zeolites can be restored upon cooling the sample to 200 K, which proves that the third signal in Figure 6(b) is a coalescence of two signals. The mixture obtained directly in the tube by shaking is very inhomogeneous with regards to the distribution of the crystallites of the two zeolites. There are three types of zone: pure RbNa-X, pure Na-Y, and a RbNa-X–Na-Y mixture. Because of diffusion, the three corresponding lines can be distinguished at 300 K. Consequently, the information obtained by ^{129}Xe NMR at 300 K is characteristic of macroscopic zones, i.e. zones containing several crystallites. The extent of these zones depends on the mean lifetime of the xenon atom in the crystallites compared with the NMR timescale. These zones can be reduced by lowering the temperature of the NMR experiment in order to obtain more and more localized information. The rate of exchange of xenon atoms between one crystallite and another must also depend on the crystallite size and, above all, on the barrier to diffusion to the external surface; all other things being equal, this barrier is related to the size of the windows of the cavities and channels.

Figure 6 ^{129}Xe NMR spectra of xenon adsorbed at 300 K and 80 kPa on RbNa-X and Na-Y treated at 673 K under 0.01 Pa: (a) before mixing; (b) after mixing; (c) mixture retreated at 673 K under 0.01 Pa

The low-temperature ^{129}Xe NMR spectra of xenon adsorbed on the zeolite in Figure 6(b) show that [in contrast to the case of the zeolite in Figure 6(c)], down to 200 K there are still four well-resolved peaks, two of them corresponding to the original RbNa-X and Na-Y zeolites. The other two signals located between those of RbNa-X and Na-Y should correspond to the $\text{Rb}_{58-x}\text{Na}_{24+x}\text{-X}$ and $\text{Rb}_x\text{Na}_{56-x}\text{-Y}$ zeolites, that result from ion exchange between the two original solids.

8 DISTRIBUTION OF THE ADSORBED PHASES

Gedeon et al. showed that the values of the slope $d\delta/dN$ and $\delta_{N \rightarrow 0}$ of the $\delta = f(N)$ plots for each degree of Na-Y hydration can be used to distinguish the water located in zones accessible or inaccessible to xenon, and to measure the volume of water in the pores.¹ Conversely, during adsorption the spectrum of the xenon probe is characteristic of the concentration gradient of the adsorbate in the sample tube and even that within the zeolite crystallite.

Pines and co-workers¹⁴ confirmed the interest in this technique by applying it to the study of the adsorption of various compounds (benzene, trimethylbenzene and hexane). Their results were confirmed by multiple quantum NMR spectroscopy.¹⁴

9 EFFECT OF EXTRAFRAMEWORK ALUMINUM

It is well known that extraframework aluminum Al_{NF} plays an important role in the catalytic properties of zeolites. The presence of these species is usually checked by ^{27}Al NMR spectroscopy of the dehydrated samples normally used in catalytic reactions, but the nature of these species is still unclear. Chen et al.¹⁵ have recently studied the nature of the Al_{NF} in MFI type zeolite by ^{129}Xe and ^{27}Al NMR. ^{27}Al NMR showed that the reference sample (R) did not contain any extraframework aluminum (Table 1). Conversely, the samples prepared in fluoride medium always contained some Al_{NF} . The quantity of Al_{NF} in the samples depends on the synthesis conditions.

The four samples studied by ^{129}Xe NMR (Table 1) have different xenon chemical shift δ dependences on the xenon loading N (Figure 7). For sample R, δ increases monotonically with N . For the samples synthesized in fluoride medium, δ first decreases and then increases with N . This indicates the presence of some strong adsorption sites inside the channels of the samples. These sites can only be more or less charged Al_{NF} species. Comparison of the number of Al_{NF} and the $\delta_{N \rightarrow 0}$

Table 1 Aluminum Concentration per Unit Cell

Sample	Total aluminum	Framework aluminum	Nonframework aluminum
R ^a	4.0	4.0	0
A	8.0	4.0	4.0
B	3.4	2.9	0.5
C	2.2	1.6	0.6

^aR, reference.

Figure 7 Variation in the chemical shift δ and the linewidth ΔH versus the number of xenon atoms (N) per gram of solids. Δ , A; $\bullet$, B; $\square$, C; * R. See Table 1

value shows that the charge on Al_{NF} increases in the order $\text{A} < \text{B} < \text{C}$. The average charge on each Al_{NF} atom depends on the amount of Al_{NF} and on the $\text{Al}_{\text{NF}}/\text{Al}_{\text{F}}$ ratio inside the zeolite.

10 CONCLUSIONS

Using ^{129}Xe NMR spectroscopy with adsorbed xenon as a probe, it is possible:

1. To determine the dimensions and the forms of the internal free volumes of zeolites without knowing their structures:¹⁶ (a) to reveal structure defects produced by, for example, dealumination, and to determine their characteristics; and (b) to calculate the short-range crystallinity, as opposed to that determined by X-ray crystallography.
2. To follow the mechanism of the synthesis and crystallization of zeolites during their preparation.¹⁷
3. To locate cations in the zeolite structure and to follow their migration or a change in their environment, depending on various factors.
4. To locate any 'encumbering' species, e.g. adsorbed molecules, extraframework species, coke formed during catalytic cracking reactions.¹⁸
5. To determine the dispersion of metals (particularly when the particles are too small to be detected by electron microscopy),¹⁹ and the distribution of the molecules adsorbed on the particles (as opposed to the mean coverage).

6. To compare the diffusion of species as a function of the size of the zeolite 'windows'.²⁰

The above list of applications is not exhaustive. Indeed this technique can also be applied to any microporous system (amorphous solid, polymer, clay, etc.), provided that one works at low temperature.

1 ZEOLITES: STRUCTURE AND PROPERTIES

Molecular sieves are a class of porous open-framework solids which includes aluminosilicates (zeolites), aluminophosphates, and related materials. Zeolites^{1–3} are built from corner-sharing SiO_4 and AlO_4 tetrahedra linked by the apical oxygen atoms to form frameworks of high internal surface area with regular channels and cavities of molecular dimensions. The zeolitic channel systems, which may be one-, two- or three-dimensional, may occupy more than 50% of crystal volume. Their microporous structure enables zeolites to be used as molecular sieves, as they can only adsorb molecules of certain size. The net negative charge of the framework, equal to the number of the constituent aluminum atoms, is balanced by exchangeable cations M^{n+} located in the channels which normally also contain water. The name ‘zeolite’ (from the Greek $\zeta\epsilon\omega$ = to boil and $\lambda\iota\theta\sigma$ = stone) was coined by Cronstedt⁴ to describe the behavior of the mineral stilbite which rapidly loses water on heating and thus seems to boil.

The general oxide formula of a zeolite is $\text{M}_{x/n}\text{-(AlO}_2)_x(\text{SiO}_2)_y \cdot m\text{H}_2\text{O}$, with $y \geq x$. According to the Loewenstein rule,⁵ which applies to all hydrothermally synthesized zeolites, aluminate tetrahedra cannot be neighbors in the framework, and so Al–O–Al linkages are forbidden. There are about 40 identified zeolite minerals (with $1 \leq y/x \leq 5$) and at least 140 synthetic species with a wide range of compositions. Figure 1 shows the secondary building units and some of the cages

Figure 1 (a) Secondary building units in zeolite structures. (o) Positions of tetrahedral silicon and aluminum atoms; oxygen atoms (not shown) lie approximately halfway between them. (b) Some polyhedra found in zeolite frameworks: the ‘ α -cage’ (26-hedron of type I); the sodalite cage; double eight-membered ring; double six-membered ring (hexagonal prism); the 18-hedron (‘ γ -cage’); the 11-hedron (‘ ϵ -cage’ or ‘cancrinite cage’)

found in molecular sieves, and Figure 2 illustrates framework structures based on the sodalite cage.

Zeolites are prepared under mild (60–400 °C) hydrothermal conditions in strongly basic media. The type and concentration of the base are important structure-directing factors, and a variety of organic bases (usually secondary or tertiary amines or quaternary ammonium compounds) have been used. A preparative method utilizing low pH which relies on F^- anions to solubilize the reactants as complex fluorides has recently been developed. Other elements, such as Ga, Ge, B, Fe, and P can substitute for Si and Al in the framework.

The physical and chemical behavior of zeolites is the subject of various monographs.^{6–10} The most important properties are the ability to adsorb organic and inorganic substances and to act as cation exchangers and catalysts. Depending on the pore diameter and the molecular dimensions, species such as gaseous elements, ammonia, alkali metal vapors, hydrocarbons, and many other organic and inorganic species may be accommodated in the intracrystalline space of dehydrated zeolites. This process, known as ‘molecular sieving’, is a powerful method for the resolution of mixtures. Commercial applications include the drying of organics, separation of hydrocarbons and of N_2 and O_2 in air, and the removal of NH_3 and CS_2 from industrial gases.

Cations neutralizing the electrical charge of the aluminosilicate framework can be exchanged for other cations from solution. Zeolites often possess selectivities for certain cations, and

Figure 2 (a) The truncated octahedron, more correctly a tetrakaidodecahedron (also known as 'sodalite cage' or 'β-cage'). (b) The structure of zeolite A is formed by linking the sodalite cages through double four-membered rings. (c) The structure of sodalite is formed by direct face-sharing of four-membered rings in the neighboring sodalite cages. (d) The faujasite structure is formed by linking the sodalite cages through double six-membered rings. For clarity, exchangeable non-framework cations are not shown

this is used for their isolation and concentration. Applications include the removal of ammonia from sewage and agricultural effluents, collection of harmful products of nuclear fission (such as $^{137}\text{Cs}^+$ and $^{90}\text{Sr}^{2+}$), water softening, and the recovery of precious elements. Molecular sieving properties of zeolites are further modified by ion exchange. Thus zeolite Na-A sorbs both N_2 and O_2 , while Ca-A sorbs nitrogen preferentially to oxygen.

However, the ability to catalyze a wide range of reactions, such as cracking, hydrocracking, oxidation, and isomerization of hydrocarbons, overshadows all other applications of zeolites. Rare-earth exchanged and hydrogen forms of some zeolites (such as zeolite Y) have a cracking activity which is orders of magnitude greater than that of conventional silica/aluminas.¹¹ The synthetic zeolite ZSM-5,¹² is a particularly powerful catalyst (Figure 3). Its high silica content (the Si/Al ratio is typically 30) gives it high thermal stability,

Figure 3 The structure of ZSM-5/silicalite

while the channel diameter is convenient for many applications. Catalytic properties of ZSM-5 include the ability to synthesize gasoline from methanol in a single step. Silicalite, a material which is isostructural with ZSM-5, but contains only small amounts of aluminum, is, by contrast to other zeolites, hydrophobic and organophilic, and is used in the removal of dissolved organics from water. The annual industrial consumption of zeolites is about 550 000 ton, of which 135 000 ton are used in catalysis, 375 000 ton as ion exchangers in detergent powders, and 40 000 ton as sorbents.

Synthetic zeolites are usually microcrystalline and, furthermore, typically contain four 10-electron atomic species (Si^{4+} , Al^{3+} , O^{2-} and Na^+), which makes their structure difficult to study by conventional methods. High-resolution solid state NMR techniques, such as magic angle spinning (MAS), gave zeolite chemistry a powerful structural tool for monitoring all elemental components of such frameworks.

2 COMPOSITION OF ZEOLITIC FRAMEWORKS AND THE NATURE OF EXTRAFRAMEWORK ALUMINUM

Framework silicon in zeolites is 4-coordinate, and thus there are five different possible environments of a silicon atom: $\text{Si}(\text{OAl})_4$, $\text{Si}(\text{OAl})_3(\text{OSi})$, $\text{Si}(\text{OAl})_2(\text{OSi})_2$, $\text{Si}(\text{OAl})(\text{OSi})_3$, and $\text{Si}(\text{OSi})_4$. For simplicity, we denote these by $\text{Si}(n\text{Al})$ where n (≤ 4) is the number of aluminum atoms connected, via oxygen atoms, to a silicon. Each type of $\text{Si}(n\text{Al})$ building block corresponds to a definite range of ^{29}Si chemical shift (Figure 4).¹³ When a ^{29}Si MAS NMR spectrum of a zeolite contains more than one peak and is correctly assigned in terms of $\text{Si}(n\text{Al})$ units, the Si/Al ratio in the zeolitic framework may be calculated from the spectrum alone. Because of the absence of Al–O–Al linkages, the environment of every aluminum atom is $\text{Al}(4\text{Si})$. Each Si–O–Al linkage in an $\text{Si}(n\text{Al})$ unit incorporates 0.25 aluminum atoms, and the whole unit contains $0.25n$ aluminum atoms. The Si/Al ratio may therefore be

Figure 4 Ranges of ^{29}Si chemical shift for $\text{Si}(n\text{Al})$ building blocks in zeolites. The $\text{Si}(4\text{Al})$ range in some synthetic sodalites containing various enclathrated salts is exceptionally wide, from -76.5 to -97 ppm

calculated directly from the ^{29}Si MAS NMR spectrum using the formula¹⁴

$$(\text{Si}/\text{Al})_{\text{NMR}} = \frac{I_4 + I_3 + I_2 + I_1 + I_0}{I_4 + 0.75I_3 + 0.5I_2 + 0.25I_1} \quad (1)$$

where I_n is the intensity (peak area) of the NMR peak corresponding to the $\text{Si}(n\text{Al})$ building unit. By comparing values of $(\text{Si}/\text{Al})_{\text{NMR}}$ with the results of chemical analysis, which gives bulk composition, the amount of extraframework aluminum in chemically modified zeolites can be calculated.

Equation (1) applies to all zeolites with framework Si/Al ratios less than about 10.^{14–16} It can also serve as a test for the correctness of spectral assignment. Its validity has been confirmed in the case of zeolites X and Y, which can be synthesized in a range of compositions. The spectra can be deconvoluted using Gaussian peak shapes, and the areas of the individual deconvoluted peaks used in equation (1). However, equation (1) cannot be applied directly to spectra containing overlapping peaks from $\text{Si}(n\text{Al})$ units of crystallographically inequivalent silicon atoms, to zeolites containing framework defects (nests of hydroxyl groups), or to dealuminated zeolites in which vacancies created by the expulsion of framework aluminum have not subsequently been resubstituted by silicon. As aluminum is removed, the number of $\text{Si}(0\text{Al})$ (i.e. $\text{Si}(4\text{Si})$) units is unchanged, while $\text{Si}(3\text{Al},1\text{Si})$ units, for example, give rise not to $\text{Si}(2\text{Al},2\text{Si})$ and $\text{Si}(1\text{Al},3\text{Si})$ units, but to $\text{Si}(2\text{Al},1\text{OH})$ and $\text{Si}(1\text{Al},2\text{OH})$ groupings, the ^{29}Si NMR peaks from which overlap with those from $\text{Si}(n\text{Al})$ groupings. Although the intensities of ^{29}Si peaks corresponding to silicon atoms linked to one or more hydroxyl groups are enhanced by

Figure 5 High-resolution ^{29}Si MAS NMR spectra of synthetic zeolites Na-X and Na-Y.¹⁵ $\text{Si}(n\text{Al})$ peaks are identified by the n above the peaks

^1H – ^{29}Si cross polarization, their individual intensities cannot be determined easily because the efficiency of the technique depends on the distance between the silicon and the hydrogen atoms.

^{29}Si MAS NMR can also be used to determine the ordering of silicon and aluminum in the framework. The areas under the peaks in the deconvoluted spectrum are proportional to the populations of the corresponding structural units in the sample. It is therefore possible to compare the experimental data (Figure 5) with the relative numbers of such units in models involving different silicon/aluminum ordering schemes. For most Si/Al ratios more than one ordering scheme is compatible with the $\text{Si}(n\text{Al})$ intensities determined by ^{29}Si MAS NMR. The choice between the various schemes is made on the basis of: (a) the degree of agreement between the spectral intensities and those required by the given model; (b) compliance with crystal symmetry requirements; and (c) minimum electrostatic

Figure 6 Two of the possible silicon/aluminum ordering schemes for zeolite Y with Si/Al = 1.67.¹⁵ (○) Silicon atoms; (●) aluminum atoms. The ratio of intensities Si(4Al):Si(3Al):Si(2Al):Si(1Al):Si(0Al) corresponding to each scheme is given in the upper right-hand corner. E is the calculated electrostatic energy for the double cage in units of $(qe)^2/a$, where a is the T–O–T distance. The asterisk denotes the preferred scheme

repulsion within the framework. Figure 6 shows the preferred ordering schemes for Si/Al = 1.67.

Many ^{29}Si spectra of natural and synthetic zeolites have been measured by various workers since the pioneering papers by Lippmaa et al.¹³ and Engelhardt et al.¹⁴ appeared. The

results for zeolites, the spectra of which can be directly assigned to Si(n Al) units, are listed in Table 1.

3 RESOLVING CRYSTALLOGRAPHICALLY NONEQUIVALENT TETRAHEDRAL SITES IN ZEOLITES

In naturally occurring zeolites, the Si/Al ratio is less than about 5, but materials with lower aluminum contents can be prepared synthetically. One might expect an uncomplicated spectrum for such materials, containing the Si(0Al) peak, sometimes with a smaller Si(1Al) resonance, depending on the Si/Al ratio. The discovery¹⁷ that the spectrum of ZSM-5/silicalite, which has a very low aluminum content and the structure shown in Figure 3, has considerable fine structure was therefore a surprise. The fine spectral detail arises from crystallographically inequivalent tetrahedral environments of the Si(4Si) sites. Figure 7(a) shows a spectrum in which as many as 19 individual lines can be separately resolved, the linewidth of the narrowest line being only about 5 Hz.¹⁸ The room temperature spectrum may be simulated by 24 Gaussian peaks, and the unit cell of ZSM-5/silicalite contains 24 inequivalent silicon sites.

X-ray diffraction (XRD) shows that silicalite can exist in the monoclinic and the orthorhombic forms. ^{29}Si MAS NMR detects minute temperature-induced variations in atomic positions^{18–21} which do not necessarily involve symmetry changes detectable by XRD. The spectra are sensitive even to small temperature changes and reveal the corresponding

structural transformations. Above 363 K silicalite contains only 12 inequivalent silicon sites, and the spectrum shown in Figure 7(c) can be simulated using Gaussian peaks of total intensity 12. Figure 7 also shows that the addition of small amounts of adsorbed organics to dehydrated silicalite induces similar changes in the spectra.

^{29}Si spectral peaks from most synthetic zeolites cannot easily be linked to specific silicon sites because the $\text{Si}(n\text{Al})$ manifolds from inequivalent sites overlap. However, when the ammonium form of a highly siliceous zeolite is heat treated in the presence of water vapor so that most framework aluminum is removed, the resolution of the ^{29}Si spectrum improves considerably.^{22,23} Figure 8 shows the spectra of several zeolites before and after hydrothermal treatment. The intensities of the two peaks in the spectra of the siliceous zeolites omega and offretite are in a 2:1 ratio corresponding to the two inequivalent tetrahedral sites in the same population ratio. Mordenite, on the other hand, has four inequivalent sites in a 2:1:1:2 population ratio, so that the peak at -115 ppm in Figure 8 is a composite.

The fact that the ^{29}Si chemical shift is related to the T–O–T angles in zeolitic frameworks is useful for structural

Figure 8 ^{29}Si MAS NMR spectra of (above) zeolites Y, omega, offretite and mordenite; and (below) their dealuminated forms²²

determination.^{22,24} Chemical shifts in framework silicates have been correlated with the mean Si–O bond distances, and relationships have been developed which are in good agreement with the results of semiempirical calculations of chemical shift. A quantum mechanical rationalization of the correlation between the ^{29}Si chemical shift in framework silicates and the change in the *s* character of the oxygen orbitals in the Si–O–Si σ bond has also been proposed (see Figure 9). The observed correlation between chemical shifts of $\text{Si}(4\text{Si})$ units and mean bond angles has been explained²⁵ in terms of a quantum mechanical model and confirmed by an extended set of experimental data consistent with relationships involving θ , $\cos \theta/(\cos \theta - 1)$, $\sin(\theta/2)$ and $\sec \theta$. These arguments have been extended to all five $\text{Si}(n\text{Al})$ units,²⁶ giving an approximately linear semiempirical relationship between the chemical shift of $\text{Si}(n\text{Al})$ peaks and the nonbonded $\text{Si}\cdots\text{T}$ distance (T = Si or Al) calculated from the T–O–T angle.

^{29}Si MAS NMR peaks in the spectra of certain zeolites lead to incorrect values of $(\text{Si}/\text{Al})_{\text{NMR}}$ when assigned to individual $\text{Si}(n\text{Al})$ units, as described above. When the difference in chemical shifts between peaks from inequivalent $\text{Si}(n\text{Al})$ units with the same value of *n* [8.4 ppm in the case of $\text{Si}_A(0\text{Al})$ and $\text{Si}_B(0\text{Al})$ in zeolite omega] is similar to the shift difference between $\text{Si}(n\text{Al})$ and $\text{Si}[(n \pm 1)\text{Al}]$ units, the effects

Figure 9 The mean T-O-T angle versus the isotropic ^{29}Si chemical shift for amorphous silica and several purely siliceous equivalents of zeolites

of aluminum substitution and crystallographic inequivalence overlap. The peaks are composites, and their intensities $I_{\text{Si}(n\text{Al})}$ cannot be read off the spectrum directly. In the case of 'as-prepared' zeolite omega, the spectrum (Figure 8) is the sum of two overlapping families of peaks. When this is taken into account, the entire spectrum can be correctly assigned and interpreted.

The chemical shift of ^{129}Xe NMR is very sensitive to the environment. When xenon is adsorbed inside a molecular sieve, its chemical shift is affected by the size and shape of the pores, by xenon-xenon collisions, by the presence of strong adsorption sites, paramagnetic species, adsorbed molecules, and phase transitions.²⁷ Most of the work in this area was done by Fraissard in Paris. While the initial hopes of predicting pore dimensions of unknown structures from ^{129}Xe NMR are still unfulfilled, the technique does provide valuable information, particularly where structural information is absent.

4 TWO-DIMENSIONAL NMR SPECTRA OF ZEOLITIC FRAMEWORKS

Two-dimensional solid state NMR techniques have been used to assign the individual NMR peaks to specific crystallographic sites. Figure 10 shows a ^{29}Si COSY-45 spectrum of the

Figure 10 Two-dimensional ^{29}Si COSY-45 spectrum of the orthorhombic form of zeolite ZSM-5/silicalite with adsorbed *p*-xylene¹⁸

orthorhombic form of zeolite ZSM-5/silicalite with adsorbed *p*-xylene.¹⁸ Of the expected 22 ^{29}Si -O- ^{29}Si connectivities, 12 are present in the spectrum. The corresponding ^{29}Si 2D INADEQUATE spectrum (Figure 11) is superior, with as many as 21 connectivities being observed.¹⁸ Excitation of a double quantum coherence has been used in double quantum filtered COSY, as in the experiment using a ^{29}Si -enriched sample of the highly siliceous zeolite ZSM-39²⁸ which contains three kinds of silicon site in a 1:4:12 population ratio. The most intense spectral peak is split into three components of equal intensity, which indicates loss of face centering of the $Fd3m$ unit cell, resulting in the disappearance of the three-fold symmetry axis.

J-scaled COSY scales up the scalar splittings between the cross-peak components, thereby enhancing cross-peak intensities and consequently improving spectral resolution between adjacent diagonal and cross peaks. The ^{29}Si *J*-scaled COSY spectrum²⁹ measured with a scaling factor of 5 at natural isotopic abundance allows the resonances from highly siliceous mordenite to be assigned unambiguously, something which cannot be done by means of one-dimensional spectra or by conventional COSY.

Figure 11 ^{29}Si two-dimensional INADEQUATE spectrum of the orthorhombic form of zeolite ZSM-5/silicalite with adsorbed *p*-xylene¹⁸

5 DEALUMINATION AND REALUMINATION OF ZEOLITES

Solid state ^{27}Al MAS NMR spectra of 'as-prepared' zeolites normally contain a single peak corresponding to four-coordinate aluminum. Its position as measured in a 9.4 T magnetic field ranges, for different materials, from about 51 to about 65 ppm from $\text{Al}(\text{H}_2\text{O})_6^{3+}$. When the correction is made for the second-order quadrupole interaction, the chemical shift is found to be related to structural parameters in a similar manner to ^{29}Si chemical shifts. ^{27}Al MAS NMR spectra of 'as-prepared' zeolites are thus much simpler than their ^{29}Si counterparts. This is a direct consequence of the fact that while five types of $\text{Si}(n\text{Al})$ environments are possible for the silicon atom, only one possibility, $\text{Al}(4\text{Si})$, exists for the aluminum. However, while the coordination of silicon in zeolites is always four-fold, aluminum can be four-, five- or six-coordinate. The latter resonates at about 0 ppm from $\text{Al}(\text{H}_2\text{O})_6^{3+}$ and is often subject to large quadrupole interactions. Quantitatively reliable ^{27}Al spectra are obtained with fast MAS at very high magnetic fields and using strong rf pulses with small flip angles.

Since Brønsted acid groups in zeolites are associated with framework aluminum, their catalytic activity depends on the

Figure 12 ^{27}Al (MAS at 12–13 kHz) and ^1H - ^{27}Al CP MAS (MAS at 8–10 kHz) NMR spectra of increasingly dealuminated (from bottom to top) zeolite HY.⁸⁰ The Si/Al ratios calculated from ^{29}Si MAS NMR spectra and the cubic unit cell parameters a_0 are indicated. Asterisks denote spinning sidebands

concentration and location of aluminum in the structure. It is often desirable to reduce the aluminum content of the zeolitic framework. Upon hydrothermal treatment of zeolite $\text{NH}_4\text{-Y}$, the process known as 'ultrastabilization', part of the aluminum is ejected from the framework into the intracrystalline space, and the vacancies are reoccupied by silicon from other parts of the crystal. As a result, thermal stability of the zeolite is greatly increased. Ultrastable zeolite Y has been examined by ^{29}Si and ^{27}Al MAS NMR.^{30–32} ^{29}Si spectra of ultrastable zeolite Y clearly show that aluminum is removed from the framework, and that the resulting vacancies are subsequently reoccupied by silicon. ^{27}Al MAS NMR shows how six-coordinate nonframework aluminum species (Al^{NF}) build up at the expense of the four-coordinate framework aluminum (Al^{F}) as the calcination temperature is increased, and ^1H - ^{27}Al CP MAS NMR spectra of dealuminated samples help to elucidate the nature of Al^{NF} .³³ Figure 12 shows that the intensity of the peaks at 0 and 30 ppm increases relative to the peak at 60 ppm. This indicates that the 30 ppm peak is a separate ^{27}Al resonance from five-coordinate aluminum.

The process of ultrastabilization of zeolite Y can be reversed by a hydrothermal treatment with aqueous solutions of strong bases.³⁴ NMR indicates that aluminum atoms originally eliminated from the framework can be subsequently reinserted into the framework. ^{29}Si MAS spectra of dealuminated samples reflect the removal of framework aluminum from the parent sample. In the spectra of samples treated with KOH the intensities of the $\text{Si}(0\text{Al})$ peaks are greatly reduced, and the intensities of the $\text{Si}(1\text{Al})$, $\text{Si}(2\text{Al})$, $\text{Si}(3\text{Al})$, and $\text{Si}(4\text{Al})$ peaks are correspondingly increased, signifying that an aluminum has reentered the framework. The spectra of realuminated samples are very different from that of the parent material, despite the fact that their overall composition is similar. This demonstrates that the silicon/aluminum distribution among the tetrahedral sites is different. ^{27}Al quadrupole nutation NMR offers further insights into the dealumination–realumination process.^{35,36}

6 NMR STUDIES OF THE STRUCTURE OF BRØNSTED ACID SITES IN ZEOLITES

The study of acidic surface sites capable of donating protons to adsorbed molecules is crucial to heterogeneous catalysis. It is vital to know the concentration, strength, and accessibility of the Brønsted and Lewis acid sites and the details of their interaction with the adsorbed organics. The Brønsted acidity of zeolites arises from the presence of accessible hydroxyl groups associated with framework aluminum ('structural hydroxyl groups'). Extensive ^1H MAS NMR measurements of zeolites have led to the assignment of the various proton resonances. ^1H NMR of static samples can probe the geometry of the Brønsted acid site and determine the Al–H distance, because the second moment of the broadline proton spectra, which is inversely proportional to the sixth power of the distance between the dipole-coupled nuclei, is dominated by the ^1H – ^{27}Al interaction.

^{15}N NMR of molecules sorbed on zeolites is also useful for the study of zeolitic acidity, as the nitrogen atom in molecules such as ammonia and pyridine binds directly to the acid site. The ^{15}N chemical shift of ammonia adsorbed in ultrastable zeolite Y does not depend on the amount absorbed and is similar to that in liquid ammonia. Consideration of the equilibrium between the surface sites and the sorbate allows the resonance shifts for the surface complexes to be obtained. The formation of pyridinium ions in ultrastable zeolites has led to direct determination of the number of interacting hydroxyl groups. Acetonitrile has also been used to characterize the interactions with the acid sites.

When trimethylphosphine is used as a probe molecule in zeolite H-Y,³⁷ the ^{31}P MAS NMR spectrum contains resonances from at least two types of $(\text{CH}_3)_3\text{PH}^+$ complex: an immobilized complex coordinated to hydroxyl protons, and a highly mobile one which desorbs at 300 °C.

7 GALLOSILICATE AND BOROSILICATE ZEOLITES

Tetrahedral aluminum and silicon in the zeolitic framework can be substituted by several other elements. (Si,Ga)-, (Ge,Al)- and (Ge,Ga)-zeolites are structurally similar to their silicon/aluminum counterparts. ^{29}Si MAS NMR spectra of (Si,Ga)-sodalites and (Si,Ga)-faujasites^{38,39} allow (Si/Ga)_{NMR} ratios to be calculated from a formula similar to equation (1), which shows that no Ga–O–Ga linkages are present. The distribution of Si(*n*Ga) peak intensities in gallosodalite is different from the Si(*n*Al) in aluminosilicate zeolites of similar Si/T ratio (T = Al or Ga), indicating that the distribution of silicon and gallium is different from the distribution of silicon and aluminum. The ^{29}Si chemical shifts in silicon/gallium zeolites span 25.1 ppm, a wider range than in the corresponding aluminosilicates (18.5 ppm).

Borosilicate ZSM-5 ('boralite') containing up to five boron atoms per unit cell has been prepared. ^{11}B spectra show that four-coordinate boron resonates at about –3.5 ppm from $\text{BF}_3\cdot\text{OEt}_2$.⁴⁰ On dehydrating boralite, the intensity of the line decreases reversibly and a second broad line appears. The width of that line, assigned to trigonal boron, is dependent on the magnetic field intensity, which indicates that the effect is quadrupolar in nature.⁴¹

8 CHEMICAL STATUS OF GUEST ORGANICS IN ZEOLITES

The declining oil reserves have stimulated efforts aimed at converting methanol (MeOH) into higher molecular weight organics over shape-selective catalysts, particularly zeolite H-ZSM-5 which is capable of converting MeOH to hydrocarbons up to C_{10} . The mechanism of the reaction is a subject of some controversy. ^1H NMR has been used⁴² to monitor the chemistry of MeOH adsorbed on ZSM-5 inside sealed capsules which can be spun in the MAS probehead.

The ^1H MAS NMR spectrum of MeOH adsorbed on zeolite H-ZSM-5 contains peaks at 4.1 and 9.1 ppm, from methyl and hydroxyl protons, respectively. The large high-frequency (downfield) shift of the latter resonance is caused by very strong hydrogen bonding and/or direct protonation of the alcohol, and serves as a measure of the proton donating ability of the solid acid catalyst: in zeolites H-Y and H-L the shifts are considerably smaller than in ZSM-5.

9 IN SITU STUDIES OF CATALYTIC REACTIONS ON ZEOLITES

^{13}C MAS NMR can probe the kind and quantity of chemical species present inside the particle in the course of the conversion of MeOH to gasoline on zeolite ZSM-5. This information is usefully compared with the composition of the gaseous products.⁴³ These experiments have: (i) identified 29 different organic species in the adsorbed phase and monitored their fate during the course of the reaction; (ii) observed directly different kinds of shape selectivity in a zeolite; and (iii) unequivocally distinguished between mobile and attached species.

The spectrum of a sample with adsorbed MeOH and maintained at 20 °C, contains a single resonance at 50.8 ppm due to MeOH (Figure 13). After heating the sample to 150 °C the spectrum is composed of two peaks, at 50.5 and 60.5 ppm, corresponding to MeOH and dimethyl ether (DME), respectively. In a sample treated at 300 °C for 35 min, MeOH and DME have been completely converted to a mixture of aliphatics and aromatics.

Two-dimensional ^{13}C spectra can determine the connectivity of carbon atoms and the number of protons attached to each carbon atom in the various products, enabling firm assignments for many resonances to be made.⁴⁴ For example, the line at –10.7 ppm in Figure 14 is split into five components with a requisite intensity ratio, which confirms that it must be due to adsorbed methane. Spin diffusion ^{13}C NMR spectra further confirm the spectral assignments and provide new details on distribution of hydrocarbons in the intracrystalline space.

10 DIRECT OBSERVATION OF SHAPE SELECTIVITY

The distribution of adsorbed species in the sample of ZSM-5 with adsorbed methanol treated at 300 °C is different from the thermodynamic equilibrium distribution and from the distribution of the reaction products.⁴³ The main species found in the adsorbed phase are *o*- and *p*-xylene, 1,2,4,5-tetramethylbenzene, 1,2,4-trimethylbenzene,

Figure 13 Solid state ^{13}C NMR spectra reveal the successive steps in the conversion of methanol to gasoline over zeolite ZSM-5. The methanol, resonating at 50 ppm, is first dehydrated to DME (60 ppm). Subsequent carbon-carbon bond formation leads to a host of aliphatic (–10 to 35 ppm) and aromatic (not shown) compounds⁴³

and 1,2,3,5-tetramethylbenzene. The fact that 1,2,3- and 1,3,5-trimethylbenzenes are not found among the products, but are present in the adsorbed phase, while the smaller 1,2,4-trimethylbenzene is found in both, demonstrates the reality of the concept of product selectivity. The two larger isomers are unable to diffuse out of the crystal. The distribution of the tetramethylbenzenes in the intracrystalline space (none of which are found in the products of the reaction at 300 °C) is equally unexpected.

11 STRUCTURE OF ALUMINOPHOSPHATE MOLECULAR SIEVES

The AlPO_4 molecular sieves, the porous crystalline equivalents of aluminum phosphate, are built from alternating AlO_4 and PO_4 tetrahedra.^{45,46} Some of them have the framework topologies of known zeolites, but many are novel structures. The various AlPO_4 structure types are listed in Table 2, and the structures of AlPO_4 -5 and AlPO_4 -11 are shown in Figure 15. Synthesized from gels containing sources of aluminum, phosphorus, and at least one organic structure-directing template, AlPO_4 materials have electrically neutral frameworks and thus no exchangeable cations. Incorporation

^aAlso known as AlPO_4 -54.

^bAn all-silica analog of AlPO_4 -5 (known as SSZ-24) has recently been synthesized.

of a silicon source into the synthesis gel results in the formation of silicoaluminophosphates (SAPOs)⁴⁷ and the incorporation of a metal Me (such as Mg, Mn, Fe, Co or Zn), into AlPO_4 and SAPO gives the MeAPO and MeAPSO sieves, respectively.⁴⁸ SAPO and MeAPO have negatively charged frameworks, and thus potential uses as ion exchangers and catalysts. In SAPO the predominant substitution mechanism is of silicon onto phosphorus sites, though pairwise substitution of silicon onto both aluminum and phosphorus sites is also possible. In MeAPO the metal substitutes onto the aluminum sites of the equivalent AlPO_4 structure. Other elements (Li, Be, B, Ti, Ga, Ge and As) have been claimed to substitute into the aluminophosphate framework to give EIAPO materials.⁴⁹ By

Figure 14 Heteronuclear two-dimensional J -resolved ^{13}C MAS NMR spectrum of zeolite H-ZSM-5 with adsorbed methanol treated at 300°C for 30 min⁴⁴

introducing more than one kind of heteroatom into the framework, or a metal and silicon simultaneously, MeAPSO and ElAPSO sieves were prepared.^{50,51}

Remarkable AlPO_4 and related materials include VPI-5, the topology of which had been predicted in advance of its being synthesized, and cloverite, a gallophosphate molecular sieve with 20-membered rings, the most porous molecular sieve prepared so far.

12 NMR STUDIES OF AlPO_4 -5, AlPO_4 -11, AND AlPO_4 -21

The AlPO_4 materials are a challenge to multinuclear solid state MR, given the wide variety of new crystal structures and the fact that they contain two different kinds of 100% abundant nuclei (^{31}P and ^{27}Al) in close proximity. Furthermore, framework aluminum in AlPO_4 can be linked to one or two oxygen species such as $-\text{OH}$ or $-\text{OH}_2$, so that some of the aluminum atoms may be five- or six-coordinate with respect to oxygen. Another challenge are the strong quadrupolar effects involving ^{27}Al as a result of which the quadrupole correction to chemical shifts is much larger than in zeolites. The aluminum and phosphorus atoms alternate in the frameworks of all AlPO_4 , so that only even-numbered

rings may be formed. However, the three allowed coordination numbers of aluminum make possible a wide range of new structures.

Table 3 summarizes the ^{31}P chemical shifts in AlPO_4 materials. Note that the precise value of the chemical shift often depends on the kind of organic template and on the water content of calcined samples. A similar table for ^{27}Al chemical shifts cannot be readily provided as the quadrupole coupling parameters, necessary if the quadrupole correction is to be made, are rarely known. Corrected ^{27}Al chemical shifts are between 37 and 48 ppm for $\text{Al}(\text{OP})_4$ sites, about 15 ppm for $\text{Al}(\text{OP})_4(\text{OH})$, and between -9.5 and -12 ppm for $\text{Al}(\text{OP})_4(\text{OH}_2)_2$ sites.⁵² There is a recent review of AlPO_4 -based molecular sieves.⁵³ A correlation between chemical shift and bond angle for AlPO_4 materials⁶⁵ relies on the comparison of mean $\text{Al}-\text{O}-\text{P}$ bond angles with ^{27}Al chemical shifts corrected for the second-order quadrupole interaction. The imperfection of the correlation⁶⁶ is probably caused by the presence of five- and six-coordinate aluminum.

The spectra of AlPO_4 -5, AlPO_4 -11, AlPO_4 -17, and AlPO_4 -31 are consistent with known framework structures. ^{31}P and ^{27}Al MAS spectra of AlPO_4 -5 each consist of a single peak.^{54,55} The ^{31}P chemical shift (about -30 ppm) is characteristic of the $\text{P}(\text{OAl})_4$ environment. The corrected chemical shift of the broad ^{27}Al peak is about 44 ppm, which is characteristic of four-coordinate $\text{Al}(\text{OP})_4$ sites. This

Table 3 Summary of ^{31}P Chemical Shifts in AlPO_4 Structures⁵³

Structure	Form	Chemical shift (ppm from 85% H_3PO_4)
AlPO_4 -5	Tripropylamine	−30.6
	Tetraethylammonium	−28.6
	Hydrated calcined	−27.8
AlPO_4 -8	Hydrated	−22.6, −25.7, −26.9, −31.1
	Dehydrated	−12.3, −30.1
AlPO_4 -11	Dipropylamine	−31.8
	Hydrated calcined	−23.4, −29.6
AlPO_4 -12	2-Imidazolidone	−6.6, −15.0
AlPO_4 -14	Isopropylamine	−5.7, −20.3, −24.3
	Piperidine	−22.1, −28.0, −30.6
	Hydrated calcined	−22.4, −23.7, −25.3, −28.1
	Dehydrated calcined	−21.9, −27.1, −32.0
AlPO_4 -14A	Isopropylamine	−19.4, −29.0
AlPO_4 -17	Not specified	−24.2
	Hydrated calcined	−29.9
	Dehydrated calcined	−29.5, −35.0
AlPO_4 -20	Tetramethylammonium	−35.2
AlPO_4 -21	Pyrolidine	−13.3, −21.1, −30.3
	Not specified	−14.8, −21.4, −26.4
AlPO_4 -25	Hydrated	−30.7
AlPO_4 -31	Not specified	−30.2
	Hydrated calcined	−29.9
	Dehydrated calcined ^a	−30.5
AlPO_4 -34	Tetraethylammonium + dipropylamine ^a	−28.5
	Hydrated calcined ^a	−27.4
AlPO_4 -35	Not specified ^a	−27.4, −32.8
AlPO_4 -37	Tetrapropylammonium + tetramethylammonium ^a	−26.4
AlPO_4 -42	Tetramethylammonium ^a	−27.5
VPI-5	Hydrated	−23.3, −27.2, −33.1
	Dehydrated	−26.6, −32.5
AlPO_4 -H3	Hydrated	−24.1, −25.9
AlPO_4 -Q	(Quartz)	−24.8
		−25.6
AlPO_4 -T	(Tridymite)	−29.5
AlPO_4 -C	(Cristobalite)	−27.1

^aMeasured in an equivalent SAPO structure.

means that aluminum and phosphorus strictly alternate in the framework. The ^{31}P peak from the calcined and partially hydrated form is split as a result of the interaction between the framework and the intracrystalline water, presumably giving rise to $\text{Al}(\text{OP})_4(\text{OH}_2)_2$ environments. Hydration produces significant amounts of six-coordinate framework aluminum which returns to four-coordination upon rehydration. Four- and six-coordinate aluminum resonate at 23–31 ppm and about −17 ppm, respectively.

AlPO_4 -11 has an orthorhombic unit cell, but the symmetry of the hydrated calcined material is lower. Adsorbates such as cyclohexane stabilize the higher symmetry form which has three distinct crystallographic sites for both aluminum

and phosphorus in the population ratio of 2:2:1. The lower symmetry form requires five sites in the population ratio of 1:1:1:1:1. Figure 16 shows that the ^{27}Al and ^{31}P NMR spectra of ‘as-synthesized’ AlPO_4 -11 show single asymmetric peaks (suggesting that more than one environment is present). The relatively low intensity resonance at −5.5 ppm in the ^{31}P spectrum is probably due to terminal $\text{P}(\text{OAl})_3\text{OH}$ sites at defects and the surface of the crystallites. The ^{31}P spectrum of the calcined and hydrated material (Figure 16) consists of two well-resolved resonances at −23.4 and −29.6 ppm in the intensity ratio of 1:4, which suggests that four of the five phosphorus sites have similar chemical shifts.

Figure 15 The structures of AlPO₄-5 and AlPO₄-11 viewed down the (001) axis

The development of double rotation (DOR), in which the sample is rotated around two different axes simultaneously and dynamic angle spinning (DAS), in which the sample is rotated sequentially about two different axes, was a major advance in the study of solids. DAS and DOR remove not only chemical shift anisotropy, but also second-order quadrupolar interactions.⁵⁶ ²⁷Al DOR distinguishes the distorted five-coordinate aluminum sites in the molecular sieve precursor AlPO₄-21. Upon calcination, AlPO₄-21 transforms to AlPO₄-25, which has two four-coordinate aluminum sites with similar isotropic chemical shifts. These cannot be resolved in an 11.7 T field, but are resolved by DOR at 4.2 T because of their different quadrupole coupling constants.

²⁷Al DOR was used⁵⁷ to monitor the nature of the phase transition of AlPO₄-11 observed when water is adsorbed. The DOR spectrum of hydrated AlPO₄-11 shows that the line at 30 ppm is indeed due to a single environment. However, the broad DOR peak from six-coordinate aluminum indicates the presence of a range of sites, suggesting that all five crystallographic sites are hydrated to a similar extent. The DOR spectrum of the dehydrated calcined sample shows only a single peak in the 11.7 T field, despite the fact that three crystallographic sites are present. This indicates that the three sites have similar chemical shifts.

13 VPI-5 AND AlPO₄-8

VPI-5 is a crystalline aluminophosphate molecular sieve containing 18-membered rings of aluminum and phosphorus

Figure 16 ²⁷Al and ³¹P MAS NMR spectra of 'as-prepared' and hydrated calcined AlPO₄-11 obtained in a 9.4 T field⁵⁷

atoms (Figure 17). The large (about 1.2 nm) channel diameter gives VPI-5 considerable potential for the separation of large molecules, and for catalytic cracking of the heavy fractions of petroleum. The material has thus been studied extensively. The room-temperature ³¹P MAS NMR spectrum of hydrated VPI-5 contains three peaks in an intensity ratio of 1:1:1 (Figure 18) and the ²⁷Al spectrum resonances from four- and six-coordinate aluminum. This is because 'as-prepared' VPI-5 is an aluminophosphate hydrate with three inequivalent sites for both phosphorus and aluminum: one of the aluminum sites is bonded to two chemisorbed water molecules, thus becoming six-coordinate. Variable temperature NMR^{58,59} (Figure 18) shows that VPI-5 undergoes a reversible phase transition to a higher symmetry structure with two ³¹P resonances in a 2:1 intensity ratio and two sites for both aluminum and phosphorus. The peaks at -23 ppm (1) and -27 ppm (2) were assigned to phosphorus atoms in 6-4 sites (P2 and P3), and the peak at -33 ppm (3) to P atoms in 4-4 sites (P1). ³¹P-³¹P spin diffusion spectra were used to establish how peaks 1 and 2 are to be assigned to particular P2 and P3 sites.⁶⁰ Each pair of ³¹P resonances gives rise to cross peaks (Figure 19) and the efficiency of spin diffusion (cross-peak intensity) decreases with increasing spinning rates. An analysis of the plot of cross-peak intensity versus the spinning rate in the light of interatomic distances known from the XRD structure showed that peaks 1, 2, and 3 should be assigned to sites P2, P3, and P1, respectively.

²⁷Al DOR spectra⁶¹ confirm that the peak from four-coordinate aluminum arises from two crystallographic sites, and the broad peak from six-coordinate aluminum from a single site. Although the two four-coordinate aluminum sites are not resolved by DOR at high fields because of their similar chemical shifts, they may be resolved at lower fields because the sites have different quadrupolar coupling constants.

Figure 17 One layer of the framework structure of hydrated VPI-5 taken from the stereoscopic view along the [001] direction showing the deviation from $P6_3cm$ symmetry.⁵⁹ Aluminum and phosphorus atoms are located at the apices of the polygons. Sites located between two fused four-membered rings are known as 4–4 sites; those located between six-membered and four-membered rings are known as 6–4 sites. P2 and P3, and Al2 and Al3 sites are inequivalent as a result of the distortion. The Al1 site is six-coordinate as a result of bonding to four bridging oxygen atoms and two ‘framework’ water molecules

Heating hydrated VPI-5 results in a transformation to $AlPO_4-8$. ^{27}Al DOR shows⁶¹ that in dehydrated VPI-5 there are also only two four-coordinate aluminum environments in the intensity ratio of 2:1. However, after a period during which the sample had been kept in a rotor which was not completely air-tight, many additional NMR resonances are found, corresponding to a partially rehydrated material (Figure 20).

Spin echo double resonance (SEDOR) allows the relative spatial disposition of spins to be deduced. By measuring the dipolar interaction between nuclei, which is inversely proportional to the cube of the internuclear distance, SEDOR probes only their immediate vicinity. ^{27}Al – ^{31}P SEDOR can measure Al–P distances in $AlPO_4$ materials.⁶² MAS NMR with dipolar dephasing has been used⁶³ for the study of mixed pairs of quadrupolar and spin- $\frac{1}{2}$ nuclei in VPI-5. Dipolar connectivities between ^{31}P and ^{27}Al were examined in both directions.

NMR spectra of $AlPO_4-8$ show single ^{31}P and ^{27}Al peaks and a small ^{31}P peak at -12.1 ppm.⁶⁴ In hydrated $AlPO_4-8$, about 34% of the aluminum is six-coordinate. The ^{31}P spectrum shows several environments, and at least five peaks are required for the simulation. The structure of dehydrated $AlPO_4-8$ calls five sites in the population ratio of 2:2:2:2:1.

14 SAPO MOLECULAR SIEVES

The general formula for a SAPO molecular sieve is $M_{(y-z)/n}[Si_xAl_yP_zO_2] \cdot wH_2O$, where $x + y + z = 1$, M is the charge-balancing cation, and the amount of silicon depends on the structure type. It is generally found that $y > z$, indicating that substitution of silicon into phosphorus sites is more frequent than substitution into aluminum sites. However, the aluminum content is often less than 50%, so that substitution of two silicon atoms for an Al + P pair must also occur. ^{29}Si NMR spectra of SAPO suffer from low signal-to-noise ratios due to the low concentration of silicon and the low natural abundance of ^{29}Si . The ^{29}Si chemical shift of SAPO-5 (isostructural with $AlPO_4-5$) is -92 ppm, which is slightly more negative than

Figure 18 Variable temperature ^{31}P MAS NMR spectra of hydrated VPI-5 in a closed rotor system⁵⁹

that for $Si(OAl)_4$ environments in zeolites, and it appears that the silicon is substituting exclusively onto the phosphorus sites of the framework. ^{27}Al , ^{31}P , and ^{29}Si NMR spectra⁶⁷ each contain single peaks, but some ^{29}Si spectra show peaks at -92 , -102 , and -108 ppm, indicating the presence of two or more silicon environments. The -102 ppm peak may originate from siliceous species on the surface of the crystallites. It also appears that, even allowing for the possible presence of amorphous silica, some regions are richer in silicon than are $Si(OAl)_4$ sites. Pairwise substitution of silicon onto aluminum and phosphorus sites seems to take place. The ^{31}P peak has the same chemical shift as in $AlPO_4-5$, which indicates that all phosphorus is in the $P(OAl)_4$ environment. Narrow ^{31}P NMR peaks from SAPO materials indicate that no Si–O–P bonds are present, and no case has yet been reported where all the silicon is present exclusively in $Si(OAl)_4$ environments.

The framework structure of SAPO-37 is that of the zeolite faujasite. There is a single ^{31}P peak at -26.4 ppm corresponding to $P(OAl)_4$ sites, and a single ^{29}Si peak at

Figure 19 Two-dimensional ^{31}P NMR spin diffusion spectra of hydrated VPI-5 recorded with MAS at 4.9, 6.5, and 10.1 kHz.⁶⁰ The three spectra are not on the same intensity scale, and so only the relative intensities within each can be compared

−90.2 ppm corresponding to $\text{Si}(\text{OAl})_4$ sites, indicating that the ideal silicon-for-phosphorus mechanism operates. Samples with high silicon content give more complicated ^{29}Si spectra, with features at −86, −90, −94, −98, −102, and −106 ppm.⁶⁸ The strongest of these, at −90 ppm, corresponds to the $\text{Si}(\text{OAl})_4$ units in pure SAPO materials, while the others correspond to $\text{Si}(\text{OAl})_x(\text{OSi})_{4-x}$ units in zeolite Y. This suggests that SAPO-37 may contain inhomogeneous growths of silicoaluminophosphate and aluminosilicate regions.

The structure of SAPO-34 is that of the zeolite chabazite. The single NMR peak of ^{29}Si at −92 ppm^{69,70} indicates that the exclusive substitution mechanism of silicon onto phosphorus sites applies, leading to the creation of Brønsted acid sites. ^{13}C MAS NMR spectra of SAPO-34 with adsorbed MeOH reveal hydrocarbon transformations upon heating the sample.⁶⁹ The major products are C_1 and C_2 organics; although formed, C_4 to C_6 hydrocarbons are too large to diffuse out through the eight-membered rings. The C_3 species are present in the product in a lower yield than expected, because the pore system is partially blocked by longer chain hydrocarbons.

15 MeAPO MOLECULAR SIEVES

The framework formula of a MeAPO sieve is $[\text{Me}_x\text{Al}_y\text{P}_z\text{O}_2]$, with $x + y + z = 1$, and $z = 0.5$, indicating that the

Figure 20 ^{27}Al NMR spectra of dehydrated and partially rehydrated VPI-5:⁶¹ (a) ^{27}Al MAS and (b) ^{27}Al DOR spectrum of dehydrated VPI-5; (c) DOR spectrum after 2 days of rehydration; (d) DOR spectrum after 23 days of rehydration

metal substitutes exclusively onto the aluminum sites of the equivalent AlPO_4 structure. MeAPOs can therefore contain Brønsted acid sites. Deviations from $z = 0.5$ are attributed to extraframework metal ($z < 0.5$) or phosphorus ($z > 0.5$). $x > 0.125$ implies the presence of $\text{Me}-\text{O}-\text{P}-\text{O}-\text{Me}$ bonds.

The ^{27}Al MAS NMR spectrum of MgAPO-20 containing 15% magnesium⁷¹ (Figure 21) shows a single $\text{Al}(\text{OP})_4$ environment, while the ^{31}P spectrum contains two major peaks at −21.1 and −28.0 ppm from $\text{P}(2\text{Al},2\text{Mg})$ and $\text{P}(3\text{Al},1\text{Mg})$ units in an intensity ratio of 1:2. The low intensity peaks come from $\text{P}(1\text{Al},3\text{Mg})$ and $\text{P}(4\text{Al})$ units. Magnesium is therefore present exclusively on aluminum sites, which makes it possible to calculate the framework composition from the intensities of the NMR peaks and to distinguish between possible ordering schemes for phosphorus, aluminum, and magnesium.

^{11}B spectra of BAPO-5 show that boron is four-coordinate, but is not necessarily a part of the framework. Only one ^{31}P peak is found, even though $\text{P}(\text{OAl})_3(\text{OB})$ sites are expected to be present. Similarly, there is no direct evidence for the presence of framework lithium in LiAPO-5 .

Figure 21 (a) ^{27}Al and (b) ^{31}P MAS NMR spectra of 'as-prepared' MgAPO-20⁷¹

16 ^2H NMR STUDIES OF MOTION IN MOLECULAR SIEVES

Since the quadrupolar interactions of ^2H are sensitive to molecular motion, the nucleus is useful for the study of molecular dynamics over a wide range of frequencies. Variable temperature studies of small organic molecules adsorbed on a series of zeolites⁷² provide information on the filling of the intracrystalline space, the motion of the adsorbed species and site-selective adsorption. The ^2H spectra of deuterated *p*-xylenes $\text{CH}_3\text{C}_6\text{D}_4\text{CH}_3$ and $\text{CD}_3\text{C}_6\text{H}_4\text{CD}_3$ on zeolite Na-ZSM-5 in terms of possible dynamic states and sorption sites of the guest molecules identify five dynamic states, the relative populations varying with the level of loading and the

temperature.⁷³ ^2H NMR results on *p*-xylene- d_6 , toluene- d_3 and benzene- d_6 adsorbed on H-ZSM-5,⁷⁴ as well as on mono-, di-, and trimethylamine on zeolites ZK-5 and Y⁷⁵ yield a wealth of dynamic information.

Examination of the dynamic behavior of water in the channels of VPI-5 leads to a motional model which applies in the temperature range 225–348 K.^{76,77} There are at least two sites for the intracrystalline water: one is bound to framework aluminum, and undergoes rotational motion about the Al–OH₂ bond, the other is a free site within the VPI-5 channels. The motion in this site is approximately isotropic, and the tumbling rate increases with temperature. The dynamic behavior of water in the temperature range 261–297 K is rather unexpected.

Multiple quantum (MQ) NMR, a 'spin counting' tool for homonuclear spin clusters,⁷⁸ is also suitable for the study of species adsorbed in molecular sieves.^{79,80} Nuclear spins are forced to act collectively via their dipolar couplings, and the resulting multiple quantum coherences are detected after conversion into observable single quantum coherences. If the system constitutes a collection of isolated clusters, the multiple quantum count reaches a plateau corresponding to the number of spins in the cluster. Figure 22 shows the results of ^1H MQ NMR experiments for hexamethylbenzene, a molecule containing 18 hydrogen atoms, adsorbed on zeolite Na-Y.⁷⁹ At lower loadings the plateau corresponds to about

Figure 22 Results of ^1H MQ NMR experiments for hexamethylbenzene adsorbed at 573 K on dehydrated zeolite Na-Y⁷⁹

one hexamethylbenzene molecule per supercage, and at higher loading to two molecules per supercage.

1 INTRODUCTION

Nitrogen has two useful nuclei for NMR spectroscopy, ^{14}N and ^{15}N , each with advantages and disadvantages. The drawbacks of these nuclei restricted the use of nitrogen NMR in the early decades of NMR spectroscopy, but Fourier transform spectroscopy, higher field magnets, larger samples, clever pulse techniques, and multidimensional spectroscopy have greatly expanded the use of nitrogen NMR.

The NMR properties of ^{14}N and ^{15}N are given in Table 1. Both nuclei have rather low magnetogyric ratios γ , so their sensitivity to NMR detection is rather low, relaxation processes are rather slow, coupling constants $J(\text{N},\text{X})$ are small and $J(\text{N},\text{N})$ values very small. Working at higher field (B_0) increases the accessibility, the signal intensity increasing as $\gamma^3 B_0^{\frac{3}{2}}$.

The spin- $\frac{1}{2}$ nucleus ^{15}N is now much used in high-resolution work, but its natural abundance is low, 0.36%. Another disadvantage is that $\gamma(^{15}\text{N})$ is negative, so NOE factors are negative, ^{15}N signals becoming more negative with proton decoupling. The maximal proton-induced NOE factor for ^{15}N is -4.93 . A disadvantageous NOE can be removed by the use of paramagnetic additives such as $[\text{Cr}(\text{acac})_3]$.

Much work uses enrichment of ^{15}N , which may not be expensive if nitric acid, ammonium salts, or nitrites can be used as starting materials. With enrichment to 99% the NMR receptivity is six times that of ^{13}C in natural abundance. Sensitivity enhancement by polarization transfer, by INEPT or related methods, is helpful, particularly if there are protons directly attached to the ^{15}N . The gain compared with ^{13}C is now the greater, since $\gamma(^{15}\text{N})$ is smaller than $\gamma(^{13}\text{C})$.

The highly abundant nucleus ^{14}N (99.64%) has nearly six times the receptivity of ^{13}C in natural abundance (1%). Nitrogen-14, however, is quadrupolar ($I = 1$), so that ^{14}N NMR spectroscopy commonly suffers from line broadening and loss of spin-spin coupling due to too-fast relaxation. The ^{14}N quadrupole moment is relatively small, however, and if the local symmetry is high or the sample viscosity low ^{14}N work can be done in high resolution. This possibility is

often overlooked nowadays, although the phenomenon of the chemical shift was uncovered very early on in ^{14}N resonance in an aqueous solution of ammonium nitrate NH_4NO_3 , which gave two sharp lines.¹

Quantitative work in ^{14}N or ^{15}N resonance is difficult because of the multiplicity of factors affecting the signal intensities, and in ^{14}N spectroscopy, the linewidth.

There is now a large volume of work in nitrogen resonance and only key or indicative references can be given. There have been two useful books on ^{15}N NMR spectroscopy.^{2,3} The review literature includes the useful compendia of nitrogen NMR work published at intervals by Witanowski, Stefaniak, and Webb,⁴⁻⁶ annual updates in appropriate chapters of the *Specialist Periodical Reports on Nuclear Magnetic Resonance*,⁷ and several articles.⁸⁻¹⁴ Experimental techniques are described in some detail in by Levy and Lichter,² Martin et al.,³ and von Philipsborn and Müller,¹³ and updates in Volumes 1-23 of *Specialist Periodical Reports on Nuclear Magnetic Resonance*.⁷

Nitrogen NMR spectroscopy affords a variety of information, with the choice of a spin $\frac{1}{2}$ or a quadrupolar nucleus, and an unusual variety of bond types, giving a range of 1350 ppm in chemical shift. Nitrogen forms bonds with all elements except those that are completely inert. Nitrogen can be found in nine stable oxidation states, with bond orders up to three, and coordination numbers up to six, the highest being in metal clusters. Moreover the shifts, coupling constants, and ^{14}N linewidths can be interpreted in terms of bond type, because of the characteristic influences of lone pair and π electrons associated with the observed nucleus, electrons which are of great importance to chemical structure and reactivity.

1.1 Nitrogen Referencing

Nitrogen NMR spectroscopy has suffered from a multiplicity of reference standards,¹⁵ but consensus now favors the use of neat liquid nitromethane as external reference. Table 2 gives standards in the literature. Arguments in favor of nitromethane are that its ^{15}N signal is little affected by proton decoupling, the ^{14}N signal is sufficiently sharp, the neat liquid is accurately reproducible, and it can be obtained enriched with ^{15}N or ^2D with negligible effect on the chemical shift.

Nitrogen referencing should be by substitution. Internal referencing is unsatisfactory because of the magnitude and variety of medium effects for nitrogen (see Section 1.3 below). These are very large when nitrogen carries a lone pair, and can be quite large in the absence of lone-pair electrons if the nitrogen carries π electrons, as in nitromethane, as shown in Table 2. If $[\text{Cr}(\text{acac})_3]$ is used as a relaxation agent, a susceptibility correction, proportional to the concentration of the paramagnetic reagent, is necessary for precise work. The susceptibility shift in an electromagnet in which the field is perpendicular to the NMR tube is half the magnitude and opposite in sign to that in a superconducting magnet.

Ammonia is unsuitable as a reference substance since the nitrogen shift and the magnetic susceptibility are both highly sensitive to hydrogen bonding, and therefore to temperature, pressure, and to the presence of other substances. Ammonia is included in Table 2 as a 'theoretical' reference standard, since the spin-rotation determination of the nitrogen shielding (σ) in the isolated NH_3 molecule¹⁶ forms the basis of an absolute scale for calculated values of σ .¹⁷ Values of the shielding for

other molecules are then obtained from the chemical shift (δ) by use of equation (1).

$$\sigma = -\delta - 135.8 \quad (1)$$

The use of ammonia or ammonium salts as reference material has been favored by those wishing to avoid negative shifts, as achieved by the use of TMS for ¹H, ¹³C, or ²⁹Si. But ammonium salts are subject to medium effects, again because of hydrogen bonding. Table 2 shows that there is a difference of

nearly 7 ppm from the nitrate to the chloride in saturated solutions. The use of Me₄NCl or Et₄NCl, which are less subject to medium effects, has not found favor. Nitrate ion, also, is susceptible to medium effects, which may be large in acidic solution because of equilibria involving nitric acid HONO₂.

Table 2 includes reference standards for solid state work. Ammonium chloride is commonly used for this, and should be the standard of choice.¹⁸ There is a large variation in the NH₄⁺ shift with different anions, particularly oxyanions, because of hydrogen bonding: Table 2 shows a difference of 17 ppm from the nitrate to the chloride.

The publications of Witanowski, Webb, and co-workers,^{5,6} which use the nitromethane standard, give nitrogen shieldings (low frequency positive) rather than shifts (δ), maintaining consistency with their earlier reports when δ and σ had the same sign, before the IUPAC sign convention for δ was adopted in 1972.

1.2 Isotope Effects and Labeling

Nitrogen-14 and ¹⁵N measurements are interchangeable, since primary isotope effects on nitrogen shifts are negligible. Bloch–Siebert shifts, arising from the negative magnetogyric ratio of ¹⁵N, are detectable in double resonance experiments, and corrections may be needed in the determination of accurate values of chemical shifts by homonuclear decoupling experiments.¹⁹

Nearest-neighbor isotope effects are not uncommon. Normally a heavier isotopic substituent increases the nitrogen shielding, with some additivity for multiple substitution. Deuteration increases the nitrogen shielding by about 0.65 ppm per hydrogen replaced in NH₃, cf. 0.5–0.7 ppm in pyridinium ion, amines, or amides. The effects are smaller in NH₄⁺, about 0.3 ppm per hydrogen.²⁰ Equilibrium isotope effects on the nitrogen shift have been reported, arising from the perturbation of tautomeric or hydrogen-bonding equilibria by deuteration.²¹

Neighbor effects of replacement of ¹⁶O by ¹⁸O are small, about 0.15 ppm per oxygen in nitrite ion, or 0.06 ppm in nitrate, but can be useful in mechanistic studies. In the oxidation of ammonia to nitrite by *Nitrosomonas europae*, or of nitrite to nitrate by *Nitrobacter vinogradsky*, the movement of the ¹⁸O label has been monitored by ¹⁵N NMR.²²

Nitrogen-15 labeling for high-resolution NMR, particularly in biomolecules, has the added advantage that the isotope can

be used as a biological tracer. The most stable radioisotope, ^{13}N , has a half-life of only 10 min.

Equilibrium isotope effects can arise unexpectedly in studies of compounds partially enriched with ^{15}N . A doubling of the nitrogen line was observed for the five-coordinate dinitrosyl complex $[\text{RuCl}(\text{NO})_2(\text{PPh}_3)_2]^+$, with 50% enrichment. This complex has one linear and one bent nitrosyl in the solid,²³ and shows bent linear fluxionality in solution.²⁴ ^{15}NO is slightly favored in the linear geometry in the $(^{14}\text{NO})(^{15}\text{NO})$ molecule, giving a slightly higher averaged shielding than the $(^{15}\text{NO})_2$ molecule. Zero-point energies are generally small for nuclei as heavy as nitrogen. This isotope effect is observable because of large differences in stretching frequency and nitrogen shift in linear and bent nitrosyls, arising from the effects of the lone pair on the bent nitrogen.

1.3 Medium Effects

The NMR properties of nitrogen carrying a lone pair are very sensitive to changes of solvent, concentration, counterion, or pH. Nitrogen NMR spectroscopy is thus a useful probe of inter- and intramolecular influences and equilibria. Medium effects on the shielding may be pronounced if hydrogen bonding or acid–base interactions occur, as Table 2 indicates. The shifts are in the same direction as protonation shifts (Section 4.1), though smaller. Hydrogen bonding to a lone pair on nitrogen commonly decreases the nitrogen shielding in saturated groups such as ammonia and alkylamines,²⁵ with sizeable deshielding from gaseous to liquid NH_3 , as from NH_3 to NH_4^+ .²⁶ Nitrogen shielding is increased, however, by hydrogen bonding through hydrogen covalently bonded to nitrogen. The nitrogen shielding in NH_4^+ increases with an increase in the strength of the hydrogen bonding to the anion,²⁷ and is particularly high in anhydrous HF .²⁸ Corresponding results are observed for protonated amines.²⁶ Hydrogen-bonded systems, therefore, show complex behavior, including proton exchange.

For nitrogen in a π -bonded system, as in nitriles RCN , or aromatic azines such as pyridine, hydrogen bonding to a lone pair on nitrogen increases the nitrogen shielding. Again, the shifts are in the same direction as protonation shifts, but smaller in magnitude. Medium effects when the nitrogen carries π but not lone-pair electrons are illustrated by the 9 ppm range shown in Table 2 for the nitrogen shift in nitromethane in different solvents. Four-coordinate nitrogen not bonded directly to hydrogen is relatively insensitive to medium effects, as expected.

Medium effects are observable also in spin–spin couplings to nitrogen because of their sensitivity to the presence of lone pairs.

Nitrogen-14 Knight shifts have been used to study solutions of alkali metals in ammonia²⁹ or methylamine³⁰ which contain solvated electrons.

2 NITROGEN-15 NMR SPECTROSCOPY

Relaxation processes are important to the design of ^{15}N NMR experiments, because of the low natural abundance, one-third of that of ^{13}C , and low NMR sensitivity, one-fifteenth of that of ^{13}C , and because ^{15}N NOE factors are negative.

Figure 1 Dipolar spin–lattice relaxation times T_{1dd} as a function of the effective molecular correlation time τ_c for different field strengths B_0 (T). A field strength of 11.74 T for ^{15}N corresponds to 500 MHz for protons. Values of τ are given in Tables 3 and 4

2.1 Nitrogen-15 Relaxation^{2–7,31,32}

Nitrogen-15 relaxation processes are qualitatively similar to those of ^{13}C in analogous environments, as in $>\text{NH}_2$ and $>\text{CH}_2$. The relative contributions of the possible mechanisms are usually different, because dipolar relaxation by protons is less efficient for ^{15}N than for ^{13}C , since $|\gamma(^{15}\text{N})|$ is only 40% of $\gamma(^{13}\text{C})$. This means that other relaxation mechanisms compete with the dipolar mechanism for ^{15}N . Representative values of relaxation times and NOE factors are given in Table 3, together with examples of particular relaxation mechanisms.

The dipole–dipole (dd) relaxation rate for nitrogen bonded to n_{H} hydrogens is given by equation (2). The relaxation time T_{1dd} depends on the changes in local fields as the molecule tumbles, and is proportional to $(1 + \omega^2 \tau_c^2)$, where ω is the resonance frequency and τ_c is the ‘correlation time’. This is the time the molecule takes to reorient itself in rotational motion, and may take an effective value in view of the complexity of tumbling motions in many molecules or groups, τ_c . Equation (2) assumes sufficient mobility that normal conditions of ‘extreme narrowing’ apply, with $\omega^2 \tau_c \ll 1$.

$$1/T_{1dd} \approx \left(\frac{\mu_0}{4\pi}\right)^2 n_{\text{H}}(\gamma_{\text{N}})^2(\gamma_{\text{H}})^2 \left(\frac{\hbar^2}{r_{\text{NH}}^6}\right) \tau_c \quad (2)$$

The contribution to the relaxation rate $(T_{1dd})^{-1}$ per hydrogen at a distance of 10 pm is then $5 \times 10^9 \tau_c$. This corresponds to T_{1dd} values of 15–80 s for nitrogen with one attached hydrogen, in small-to-medium-sized molecules in common solvents. Liquid pyrrole has $T_1 = 40 \text{ s}$ ³³ and aqueous acetamide $T_1 = 14 \text{ s}$.³⁴

As molecular tumbling slows down beyond the ‘extreme narrowing’ region, it reaches the Larmor precession frequency below which spin–lattice relaxation is less effective as τ_c increases.³⁵ The value of T_{1dd} falls to a minimum near $\omega \tau_c = 1$ and then increases depending on the field strength B_0 , as shown in Figure 1. There are concomitant changes in the NOE.

Such a decrease in T_{1dd} for longer correlation times is advantageous to the study of biomolecules such as lysozyme, a globular protein of molecular mass 14 600 Da, for which a

^aMeasurements were made at ambient temperatures (300 ± 3 K) if no other temperature is given.

^bValues of τ_c are in ps (10^{-12} s).

^cRelaxation mechanisms are given in decreasing order of their contribution: dd = dipole–dipole (intra- or intermolecular), sr = spin–rotation, (int) = internal, sa = shielding anisotropy, e = electron–nuclear, sc = scalar coupling, pe = proton exchange.

^dTPP is *meso*-tetraphenylporphyrin.

correlation time of 8.5×10^{-9} s was measured in aqueous solution. Lysozyme, hemoglobin, vitamin B₁₂, or transfer-ribonucleic acids could be studied in natural abundance of ¹⁵N at 18.25 MHz (180 MHz for protons).³⁶ Internal motions, such as segmental rocking or spinning of a pendant group such as −NH₃⁺, reduce the effective τ_c for the nitrogens concerned.

Working at higher fields is thus detrimental for biomolecules, since the $T_{1\text{dd}}$ minima shift to smaller values of τ_c with an increase in B_0 (Figure 1).

Unlike T_1 , the transverse (spin–spin) relaxation time T_2 decreases steadily with an increase in τ_c to a limiting value in the solid state determined by dipolar interactions. Uncertainty broadening may be a hazard, since $T_{2\text{dd}}$ has an additional τ_c -dependence which is independent of ω . Deuteration was used to improve ¹⁵N resolution in hemoglobin studies through the γ^2 -dependence of the dipolar relaxation rate.³⁷

The microviscosity η' is important, since the correlation time is proportional to η'/kT . In work with smaller molecules the

relaxation rate may be doubled by the use of more viscous solvents such as dioxan or ethanol, rather than chloroform or acetone. Dipolar relaxation has been speeded up by the use of viscous additives, such as glycerol in aqueous solution, or polystyrene in toluene for organic-soluble molecules.³⁸ Higher macroviscosities are unlikely to broaden the lines by an increase in the transverse relaxation time T_2 since this depends on the microviscosity, which is smaller than the macroviscosity by a factor of six to seven.³³ Cooling is particularly effective as it increases the viscosity (depending exponentially on the temperature) and the sensitivity and the correlation time.

Relaxation times may be quite long in the absence of nearby hydrogen or of alternative mechanisms of relaxation. Neat liquid nitrobenzene and benzonitrile have T_1 values in excess of 400 s, compared with 140 s for aqueous nitrate (Table 3).³⁹ ‘Exposed’ nitrogen, as in a cyano group or in aromatic azines such as pyridine, experiences intermolecular dipolar relaxation

in which T_{1dd} is directly proportional to the distance of closest approach of the hydrogen.

Electron–nuclear relaxation, however, is likely to be present. This is promoted very efficiently by paramagnetic impurities, of iron or nickel for example, to which basic nitrogen is very sensitive. Rigorous purification is necessary for measurements of nitrogen relaxation times,³⁴ although the effects of dissolved oxygen are small.

Paramagnetic additives may be useful for quantitative studies, to quench dipolar relaxation and the NOE.³⁴ Susceptibility corrections may then be necessary for accurate shift measurement (Section 1.1). With $[\text{Cr}(\text{acac})_3]$ there is some hydrogen bonding between hydrogen attached to nitrogen and carbonyl groups in the ligand. Gadolinium complexes such as $[\text{Gd}(\text{acac})_3]$ interact quite strongly with basic nitrogen, and can be used for spin-labeling.

The spin–rotation (sr) mechanism is effective in the relaxation of ^{15}N in small molecules or ions, such as gaseous NH_3 ,⁴⁰ aqueous nitrate or nitrite ion,⁴⁰ or liquid dinitrogen; also in freely rotating substituents, nitro⁴⁰ or nitrite⁴¹ for example (Table 3). The sr mechanism becomes more efficient at higher temperatures, the rate being proportional to kT .

Shielding anisotropy (sa) relaxation is important for linear groups such as $-\text{C}\equiv\text{N}$, as the aqueous ion CN^- ,⁴² in nitriles,⁴⁰ or as a ligand; the same applies to dinitrogen⁴³ (precise work with metal complexes is difficult because of the difficulty in excluding paramagnetic ions). This mechanism is efficient also in planar groups, such as nitro or nitrate, and azine nitrogen as in pyridine (Table 3). The rate is very sensitive to the shielding anisotropy $\Delta\sigma$, being proportional to $(\Delta\sigma)^2$; values of $\Delta\sigma$ are discussed in Section 5. This mechanism is very effective at higher fields, the rate being proportional to B_0^2 . Table 3 shows the increase in relaxation rate with an increase in the applied field for the cyanide ion and nitrobenzene.⁴⁴

In some molecules all three mechanisms (sa, dd, and sr) are operative, as for pyridine and *trans*-azobenzene. Another mechanism of importance for ^{15}N is afforded by proton exchange (pe) in hydrogen-bonded systems, magnetization being transferred by the migrating proton. Table 3 includes an example of the fast relaxation of ^{15}N by scalar coupling to fast-relaxing ^{14}N in $^{14}\text{N}^{15}\text{N}$ gas.⁴⁵

In the solid state, the dipolar relaxation of ^{15}N is fast in NH_4Cl .⁴⁶ Relaxation is faster still in *meso*-tetraphenylporphyrin (TPP), in which two hydrogens exchange between the central four nitrogens, a process long known in solution. Studies of T_1 and NOE show that the unprotonated nitrogen relaxes by the sa mechanism, by dipolar interaction with the protons on the other nitrogens, and through proton exchange.⁴⁷

2.2 Nitrogen-15 NOE Factors⁴⁸

If ^{15}N is wholly relaxed by $^{15}\text{N}/^1\text{H}$ dipolar interactions, the NOE factor (η), with broadband proton decoupling, is given by equation (3):

$$\eta_{\text{max}} = \gamma(^1\text{H})/2\gamma(^{15}\text{N}) = -4.93 \quad (3)$$

The negative sign corresponds to inversion of the signal. (Note the use of the symbol η for the NOE factor and also for the viscosity.) The net enhancement is then -3.93 , better than the ^{13}C value of 2.99. There is a further gain in signal height from the collapse of multiplets.

The NOE factor observed depends on the proportion of the relaxation that takes place by $^{15}\text{N}/^1\text{H}$ dipolar interactions:

$$\eta_{\text{obs}} = (I - I_0)/I_0 = -4.93(T_1)_{\text{obs}}/T_{1dd} \quad (4)$$

If this proportion is small the signal intensity (I) is diminished and the signal vanishes if the proportion is 20% ($I = 0$, $\eta_{\text{obs}} = -1$).

Five mechanisms have been identified by which ^{15}N signals can be lost on proton decoupling.⁴⁹ The dipolar process diminishes when more efficient modes of relaxation are possible, as in the presence of paramagnetic compounds, or averaging by fast chemical exchange. Table 3 shows many molecules for which the full NOE factor -4.93 is not achieved under the conditions of the experiment.

The diminution in T_{1dd} as correlation times τ_c increase beyond the ‘extreme narrowing’ limit, illustrated in Figure 1, also diminishes the NOE, the more so at higher resonance frequencies ω . With large or highly associated molecules, the NOE may be unfavorable,⁵⁰ and working at higher fields disadvantageous. The maximal NOE factor shrinks from -4.93 to -0.12 , and the signal is annulled for a correlation time of 1 ns at 11.7 T (500 MHz for protons). The NOE may be removed by gated decoupling or by paramagnetic additives, promoting electron–nuclear relaxation.

The NOE has various uses, i.e. as a measure of molecular mobility or dynamics, in spectral assignment, and to locate spin labels. A disadvantage is the difficulty in using signal intensities in quantitative work.

2.3 Nitrogen-15 Sensitivity Enhancement

Nitrogen-15 sensitivity is enhanced by the use of larger samples, higher fields, lower temperatures, and proton decoupling and the NOE, if favorable. Valuable enhancements are obtained by the use of special pulse sequences transferring polarization (magnetization) from a more sensitive nucleus, usually the proton, to which the ^{15}N nucleus is coupled. A 10-fold enhancement is given by the $\gamma(^1\text{H})/\gamma(^{15}\text{N})$ ratio, and the sign of γ is now immaterial. Further amplification may be gained by faster pulsing, allowed by the faster proton relaxation.

In the liquid phase magnetization can be transferred via spin–spin coupling to protons, if this is resolvable. Such methods have the advantage over NOE enhancement of not requiring the relaxation mechanism to be dipolar. They include J cross polarization (JCP), selective polarization transfer (SPT), ‘insensitive nuclei enhanced by polarization transfer’ (INEPT), ‘distortionless enhancement by PT’ (DEPT), and developments of these.^{2,3,7,51} In $>\text{NH}$ systems, as in bilirubins for example,⁵² measurements may be made in this way in natural abundance of ^{15}N . Longer-range couplings also may be used in azaaromatic or peptide systems. The methods are used to determine coupling constants and their signs, to establish connectivities, to distinguish nitrogens bearing different numbers of hydrogens, to correlate signals of different nuclei, to investigate relaxation processes, and to measure relaxation times.

Multiple quantum methods involving a double transfer of magnetization, $^1\text{H} \rightarrow ^{15}\text{N} \rightarrow ^1\text{H}$, provide substantial improvements in ^{15}N sensitivity because of the detection in proton spectra. They are increasingly used to correlate ^1H and ^{15}N shifts in two-dimensional (2D) spectra through spin–spin

coupling pathways.⁵³ Polarization transfer from ^{15}N to ^1H decreases ^1H sensitivity, but has been used in 2D spectroscopy to assign all the ^{15}N signals of a labeled tRNA by heteronuclear decoupling difference spectroscopy.⁵⁴

A variety of 2D, 3D, and even 4D experiments in correlation spectroscopy (COSY) are now being used to correlate ^{15}N , ^{13}C , and ^1H resonances.⁵⁵ A 3D experiment may correlate ^{15}N resonances with those of differently connected protons, as in $^{15}\text{N}^1\text{H}-\text{C}^1\text{H}$ groups in biological systems. 4D techniques are being used in protein research, as in the correlation of ^1H , ^{13}C , ^{15}N , and ^{13}CO resonances in calmodulin.⁵⁶

Comparable experiments have been performed in which magnetization is transferred from ^2D , ^{19}F , or ^{31}P to ^{15}N . The faster relaxation of the deuteron, by the quadrupolar mechanism, compared with the proton, may outweigh the disadvantage of the relatively small magnetogyric ratio of ^2D . In the solid state, cross polarization (CP) is used to transfer magnetization via dipolar couplings. (See *Organic Chemistry Applications*.)

3 NITROGEN-14 NMR SPECTROSCOPY

The ^{14}N quadrupole moment is relatively small ($Q = 0.0199 \times 10^{-28} \text{ m}^2$) and a large volume of NMR work has been done in ^{14}N resonance, particularly when ^{15}N spectroscopy was less accessible. In some respects, ^{14}N work is coming into its own again as modern techniques turn the ^{14}N nuclear quadrupole interaction to advantage, to spread nitrogen spectra over a large range, more than compensating for quadrupolar line broadening.^{57,58}

Nitrogen-14 linewidths vary quite widely, depending on the local electronic symmetry of the ^{14}N nucleus and its mobility. High-resolution spectroscopy is possible if the local electronic symmetry and the mobility are both high. Sharper lines may be obtained if the sample viscosity can be reduced by the use of higher temperatures or more mobile solvents (Section 3.2). Fast relaxation may be advantageous in allowing rapid pulsing. The variability of ^{14}N linewidths must be taken into account in quantitative work.⁵⁹

^{14}N NMR is a useful probe of molecular dynamics, because of the sensitivity of the linewidth to local motions. Nitrogen-14 induced relaxation of protons in peptide ($^{-14}\text{NH}-\text{CO}-$) groups in protein backbones which exchange with water protons is of importance to proton NMR tomography.⁶⁰

3.1 Nitrogen-14 Quadrupolar Relaxation⁶¹

The ^{14}N linewidth $W_{1/2}$, the width at halfheight of the (Lorentzian) line or component of a multiplet, is proportional to the relaxation rate and to the square of the nuclear quadrupole coupling constant (NQCC) χ [equation (5)]. The quadrupolar relaxation time T_q is equal to $T_1 = T_2$ in the extreme narrowing regime ($\omega^2\tau_c \ll 1$), i.e. for mobile species.

$$\pi W_{1/2} = 1/T_q = \frac{3}{8}\chi^2(1 + \eta^2/3)\tau_q \quad (5)$$

where

$$\chi = e^2qQ/\hbar \text{ (in radians)} \quad (6)$$

In equation (6), eq (or more precisely eq_z , where $|q_z| \geq |q_x| \geq |q_y|$) is the electric field gradient (efg) at the nucleus. The quantity η is now the asymmetry parameter, equal to $(q_x - q_y)/q_z$. Linewidths are very sensitive to χ but less sensitive to η , since $\eta \leq 1$ by definition. The quantity $\tau_q = \tau_c$ is the effective correlation or reorientation time of the ^{14}N quadrupole. NQCC values are obtained from the NQR spectroscopy of solids, from the microwave spectroscopy of gases, and by NMR methods.⁶² Values of χ are usually similar in the liquid or solid phase of a particular species, and are about 15% greater in the gas phase.

The ^{14}N electric field gradient is largely determined by the disposition of the valence p electrons. In highly symmetric environments, in which there is no static efg, quadrupolar relaxation is mediated by collisional and vibrational distortion of molecules or ions.^{63,64} Although the ^{14}N quadrupole moment is relatively small, relaxation of ^{14}N is almost invariably by the quadrupolar mechanism because of the χ^2 -dependence of the rate. Even in the highly symmetric location in solid NH_4Cl , the dipolar relaxation mechanism is observed only below 220 K.⁶⁵ Above 220 K, rotation of the ammonium ion in the lattice switches the efg at the ^{14}N nucleus, so relaxing the nuclear electric quadrupole and the nuclear spin. In aqueous solution, ^{14}N in NH_4^+ shows zero NOE because of transient efgs arising from the buffeting by solvent dipoles.⁶⁶ In paramagnetic cyano complexes $\text{K}_3[\text{M}(\text{CN})_6]$, where $\text{M} = \text{Cr}, \text{Mn}, \text{Fe}$, the ^{14}N relaxation was found to be wholly quadrupolar, even though the nitrogen shifts were determined by the contact interaction.⁶⁷

3.2 Nitrogen-14 Linewidths

Table 4 lists the ^{14}N linewidths, relaxation times, NQCC values χ , and correlation times for a range of compound types, grouped by the coordination number of the nitrogen and in approximate order of increase in linewidth. Nitrogen-14 lines may be quite sharp, with χ values of 1 MHz or less, if the nitrogen is in a highly symmetrical location, as in NH_4^+ ,⁶¹ NF_4^+ (tetrafluorammonium),²⁸ or tetraalkylammonium (R_4N^+) species.⁶⁸ Nitrogen-14 spectra were obtained in the first measurement of interstitial nitrogen, in the trigonal prismatic clusters of cobalt and rhodium⁶⁹ $[\text{M}_6\text{N}(\text{CO})_{15}]^-$, before the ^{15}N lines were obtained with 97% enrichment. For the rhodium cluster there was some resolution of three lines of the septet, with $^1J(\text{Rh}, ^{14}\text{N}) \approx 4 \text{ Hz}$. The ^{14}N and ^{15}N lines were similar in width for the cobalt cluster because of line broadening by the ^{59}Co quadrupole and unresolved coupling.

Nitrogen-14 lines are sharp also if the nitrogen is centrally placed in linear groups such as the nitronium ion (NO_2^+)^{6a} or azide ion (N_3^-),⁷⁰ or in trigonal planar groups such as nitrate ion,⁷¹ all highly mobile in solution.

Linewidths may be small if the substituents on nitrogen do not differ greatly in electronegativity, as in the linear molecules NVO^{72} and isonitriles RNC .^{73,74} Compared with the nitrate ion, broader lines are observed for ethyl nitrate, nitromethane,^{75,76} or NOF_2^+ ,²⁸ broader still for pyridine N -oxide,⁷⁷ PhNO_2 ,⁷⁸ or dimethylamide,⁷⁹ more bulky molecules. The line is very broad for the oxygenated nitrogen in azoxybenzene, which carries a π bond, a single bond, and a double bond.⁸⁰ The fluorammonium ion, NH_3F^+ , with substituents of very different electronegativity, gives a broad

^bObserved linewidths may contain unresolved couplings.

^cViscosity.

^dValues of τ_q are in ps (10⁻¹² s); compare the values measured in ¹⁵N resonance (Table 3). Where three values are given, these correspond to $\tau_{x,y,z}$, where the *x* direction is that of the axial bond to nitrogen and the *y* direction is in the molecular plane.

line²⁸ with some broadening being due to the hydrogen bonding in the HF solvent.

Long-chain tetraammonium species give very broad lines. The ¹⁴N relaxation properties of Me₃N groups have been used to study reorientational motion. In the surfactants C_nTAC and C_nTAB, the two motions reported in Table 4 are rotation within a micelle and a slower diffusional motion.^{81,82} In biomolecules, the choline Me₃N headgroup is a useful probe of orientation, as in studies demonstrating a phase transition in the phospholipid sphingomyelin, from bovine brain membrane,⁸³ or changes in phosphatidylcholine in the presence of anaesthetics.⁸⁴

The efg and the linewidth are greatly increased by the presence of a lone pair on the nitrogen. This electronic charge is close to the nucleus, even closer if the substituents on the nitrogen are highly electronegative as in NF₃, in which the ¹⁴N NQCC is very large.²⁸ Linewidths are sizeable generally for pyramidal nitrogen, as in amines,⁸⁵⁻⁸⁸ and for bent (two-coordinate) nitrogen, as in organic isocyanates,⁸⁹ nitrites,⁷⁵ and pyridine.⁹⁰

The lone pair on terminal (one-coordinate) nitrogen is less effective in line broadening because of the axial symmetry.

Again, linewidths increase with an increase in electronegativity of the nearest neighbor, from dinitrogen^{42,47} to nitrile species RCN⁹¹⁻⁹⁵ and to the nitrosyl ion NO⁺.²⁸ In dinitrogen oxide, N₂O, the ratio of the linewidths for the two nitrogens in solution is as expected from the NQCCs determined by microwave spectroscopy in the gas phase.⁷³

Similarly, protonation or coordination reduces NQCC values. They are reduced also by delocalization of a lone pair in conjugated systems, as in pyrrole,⁹⁶ and delocalization which flattens a pyramidal group, or increases the bond angle for two-coordinate nitrogen. The effects of bond-angle distortion are evident for nitrogen in three- to seven-membered rings.⁶⁹ Hydrogen bonding to a lone pair on nitrogen slightly reduces the NQCC, while hydrogen bonding of a lone pair on nitrogen has the opposite effect, as shown by pyrrole in pyridine.⁹⁶

Certain ligands in metal complexes are usefully studied by ¹⁴N NMR study, so long as the molecules are not too bulky or associated. Linear ligands may give sharp lines because of the axial symmetry at nitrogen. Sharp lines were observed for the imido (nitrene) ligand (=NR) in *trans*-[WF₄(NMe)L] complexes,⁹⁷ and shifts were measurable for

the imido complexes of Ta, W, and Os, even with quite bulky R groups such as SiMe₃, helped by internal mobility.⁹⁸ Despite the ⁹⁵Mo quadrupole, ¹⁴N lines were readily resolved in dialkyldithiocarbamate complexes of molybdenum with NO or NS coligands,⁹⁹ and ⁹⁵Mo–¹⁴N couplings were resolved for η^5 -cyclopentadienyl complexes with NO and CO ligands.¹⁰⁰ Quite sharp lines were observed in PdCN^tBu complexes.¹⁰¹ The kinetics of electron transfer reactions between ferricyanide and ferrocyanide ions in aqueous solution were studied by ¹⁴N linewidth measurements.¹⁰²

Otherwise, ¹⁴N lines are usually broad for ligating nitrogen, whether with bulky (e.g. phosphine) coligands, of the difference in electronegativity of the nearest neighbors: examples in Table 4 are the ammine and ethylene diamine complexes of cobalt.^{103,104}

There is a direct dependence of ¹⁴N linewidth on the sample viscosity for a wide range of molecules. Linewidths may be halved by the use of diethyl ether solvent instead of chloroform, or acetone instead of water. Fluoronitrogen compounds are readily studied by ¹⁴N NMR because of their high mobility.²⁸ Resolution of *J* couplings to quadrupolar nuclei has been achieved for super- or near-critical fluids in standard thick-walled tubes, including ¹⁴N¹⁴N and ¹⁴N¹⁷O couplings in liquid N₂O.¹⁰⁵

Warming a sample is particularly helpful, the viscosity decreasing exponentially with increase in temperature. The rotational correlation time for a spherical molecule is given by the Stokes–Einstein–Debye theory as

$$\tau_c = V\eta/kT \quad (7)$$

where η is the viscosity and *V* is the molecular volume, equal to $4\pi r^3/3$.³³ equation (7) gives a correlation time of 1 ps for a molecule of radius 1 Å at 300 K for $\eta = 1$ cP. Observed rotational motions are faster by a factor of about 6, and a microviscosity η' that is one-sixth of the bulk viscosity is envisaged.

Direct dependence on viscosity breaks down for molecules that are small, linear, or flat, rotating or librating between neighboring molecules. Molecules rotating relatively freely in the liquid phase have a reduced temperature dependence of τ_c , according to equation (8), where *I* is a moment of inertia:

$$\tau_c = \frac{1}{2}(\pi I/3kT)^{1/2} \quad (8)$$

Quadrupolar relaxation in ionic solutions⁶⁷ is mediated by the rotations of ions and solvent dipoles, by collisions, and by molecular vibrations. In mobile solutions, with $\omega^2\tau_c \ll 1$, the relaxation rate is given approximately by equation (9):

$$\pi W_{1/2} = 1/T_q = 8\pi(\beta e q Q/\hbar)^2 \left[\mu_s^2 c_s r_0^{-5} \tau_s + \sum_i z_i (3a_i^3)^{-1} c_i \tau_i \right] \quad (9)$$

Terms with the subscript *s* give the effects of solvent dipoles, and with the subscript *i*, the effects of ionic charges. The *c* terms are concentrations, *r*₀ and *a_i* are distances of closest approach, μ_s is the dipole moment, *z_i* are ionic charges, and τ_s , τ_i are the respective correlation times. Further terms are needed for hydrogen bonding or exchange processes. If D₂O replaces H₂O, the motions are slowed by the higher mass and stronger hydrogen bonds.

The electric field gradient is now amplified by a factor given by equation (10), as

$$\beta = P(1 - \gamma_\infty) \quad (10)$$

where $P = (2\epsilon + 3)/5\epsilon$ is the polarizability of the solvent, with dielectric constant ϵ . The quantity $(1 - \gamma_\infty)$ is the Sternheimer antishielding factor which represents the distortion of the inner electron shells by electric field gradients in the valence shell. Experimental determinations are rare: values of 9 and 22–26 have been determined for $(1 - \gamma_\infty)$ in solid NH₄Cl, compared with a calculated (ab initio) value of 6.8.¹⁰⁶

4 PATTERNS OF NITROGEN SHIFTS

The large literature of nitrogen shifts is reviewed regularly.^{6,7} Nitrogen shifts in diamagnetic compounds cover a range of 1350 ppm, over three times the carbon range. The comparison with carbon is helpful since carbon shielding patterns are well known. The greater range for nitrogen arises from its greater electronegativity, and its ability to carry lone-pair electrons with s character, which carbon does very rarely.

The major determinants of nuclear magnetic shielding are demonstrated by expressions such as equation (11) for the paramagnetic term σ_p , which dominates the nitrogen shift in diamagnetic compounds. The negative sign of σ_p (ppm) represents deshielding, so the shift δ increases with the absolute magnitude of σ_p .

$$\sigma_p \approx -\frac{\mu_0}{4\pi} \frac{e^2}{2m_e^2} \langle r^{-3} \rangle_{2p} \frac{\langle 0 | \mathbf{L}^2 | 0 \rangle}{\Delta E} \quad (11)$$

Equation (11) embodies an ‘atom-in-a-molecule’ approximation^{107,108} in a simplified form. It does not give accurate results, but is useful in showing the three factors of importance to the shielding. The first is the radial term $\langle r^{-3} \rangle_{2p}$, where *r* represents the radius of the 2p electron on the observed atom. The value of the radial term for the free atom, which can be viewed as a scaling factor for the shifts of a particular nucleus, is twice as large for nitrogen (2.46 a.u.) as for carbon (1.23 a.u.);¹⁰⁹ the more electronegative atom holds its valence p electrons closer to the nucleus, giving a larger paramagnetic shift.

The second factor is the term in $\mathbf{L}^2$ representing the angular momentum which allows the electronic charge to circulate in a magnetic field, so as to reinforce the field. This paramagnetic circulation opposes the free diamagnetic circulation, which is fully realized only in the free atom or round the axis of a linear molecule. The paramagnetic circulation requires an asymmetry of charge in the valence shell of the observed atom, i.e. in the p orbitals of a second-row element such as carbon or nitrogen. The angular momentum term in equation (11) is analogous to the *Q* terms in the theory of Karplus and Pople, expressing imbalance of charge, or the *P_u* term in the theory of Jameson and Gutowsky.¹⁰⁹ Electronic asymmetries which potentiate the paramagnetic circulation are small in highly symmetric environments, as in CH₄ or NH₄⁺, but may be large for two-coordinate nitrogen carrying a lone pair.

The third factor, ΔE , is an effective excitation energy for the paramagnetic circulation. This can be considered to arise from virtual excitations of p → p type, which may be $\pi \leftrightarrow \sigma$

(i.e., $\pi \rightarrow \sigma^*$ or $\sigma \rightarrow \pi^*$), $n \rightarrow \pi^*$, or $\sigma \rightarrow \sigma^*$ from one bond to another, as the magnetic field mixes into the ground state those excited states which allow circulation of charge. Excitation energies vary more widely for nitrogen than for carbon, since lone pair (n_N , or nonbonding) electrons afford a high lying HOMO, and LUMOs involving nitrogen are low lying because of the electronegativity of nitrogen. The frontier orbitals in question are those appropriate to charge rotation (e.g. $n_N \rightarrow \pi^*$, but not $\pi \rightarrow \pi^*$), and the terms HOMO and LUMO may represent more than one High lying Occupied MO, or Low lying Unoccupied MO, when more than one excitation contributes significantly to the deshielding. These magnetic-dipole-allowed excitations are normally forbidden in the electronic spectrum. They are weakly allowed in $n_N \rightarrow \pi^*$ excitations in which there is a component of the $s \rightarrow p$ type, giving the well-known long wavelength bands of the azo chromophore, for example. More precise formulations of equation (11) embody a summation over the magnetically active excitations.

Equation (11) shows that the deshielding (δ) is the greater the closer the paramagnetic circulation to the nucleus (the more electronegative the substituents), the smaller the energy ΔE of the virtual excitation (the HOMO–LUMO or frontier orbital gap for charge circulation), and the greater the imbalance of charge in the valence shell. All three factors are important when extremes of high or low shielding are observed.

In isoelectronic (isostructural) locations, the shieldings of nitrogen and carbon, indeed the shielding tensors, show similar shielding patterns, with scaling according to the radial factors. Similar patterns are evident in Figure 2, which compares nitrogen and carbon shift ranges for some standard bond types. Figure 3 gives nitrogen shift ranges for compounds formed with main group elements, and Figure 4 is a comparable chart for ligands in transition metal complexes.

4.1 Nitrogen Compared with Carbon

In Figure 2 the nitrogen and carbon charts are scaled by the 2:1 ratio of the radial terms $\langle r^{-3} \rangle_{2p}$ for the free atoms, to make the shifts readily comparable. A major difference between the nitrogen and carbon charts is the extension of the nitrogen range to lower shielding for π -bonded nitrogen carrying a lone pair of electrons, as in azo (diazene) groups $RN=NR$ or nitroso compounds RNO .

High carbon or nitrogen shielding is observed in CH_4 or NH_4^+ because of the electropositive substituent hydrogen ($\langle r^{-3} \rangle_{2p}$ is small), the high electronic symmetry in the valence shell (the angular momentum term is small), and the high energy of the $\sigma \rightarrow \sigma^*$ excitations (ΔE is large).¹¹⁰ The energy of the $n \rightarrow \sigma^*$ excitation is also high in ammonia, and the lower nitrogen shielding in NH_4^+ compared with NH_3 is largely attributable to the positive charge on the nitrogen, increasing the radial term and excitation energies. Nitrogen shifts are found to correlate with the atomic charges estimated for nitrogen in amines, nitro compounds, isonitriles, and azines.¹¹¹

Nitrogen is strongly deshielded as an interstitial atom in the metal cluster carbonyls such as $[Rh_6N(CO)_{15}]^-$, a trigonal prism, and $[Ru_6N(CO)_{16}]^-$, which is octahedral.⁷⁰ The interstitial carbon in the corresponding clusters is even more strongly deshielded, as shown in Figure 2. The

deshielding is unexpected in view of the high symmetry and the electropositive and heavy neighbors. Carbon in the corresponding clusters is even more strongly deshielded. Indeed, the deshielding increases with compression of the interstitial atom in the cluster, as observed in some other kinds of cages.¹¹²

The nitrogen shifts in alkylamines and hydrochlorides can be expressed by additive substituent parameters,¹¹³ as for carbon in alkanes. For nitrogen shifts, as for carbon shifts, the increments for each C_α or C_β substituent arise from inductive effects, while the increments for C_γ substituents arise from steric and conformational effects. Substituent parameters have been developed for other compound types,^{2,3} including peptides, but correlation spectroscopy is now used to assign nitrogen resonances.

Lower shielding is generally observed in multiply bonded compared with singly bonded compounds, because of the lower electronic symmetry of the observed atom when π and σ bonds are present and the lower energies of $\pi \leftrightarrow \sigma$ in comparison with $\sigma \rightarrow \sigma^*$ excitations. Figures 2–4 show that quite high shielding is observed for nitrogen as the central atom in a linear group, as in $MeNC$, NNO , or NO_2^+ , or carbon in $MeCN$, NCO^- , or CO_2 . The shielding is relatively high because of the free diamagnetic circulation about the axial direction, as in the noble gas compounds $RC\equiv N-XeF^+$, measured in ^{14}N resonance,¹¹⁴ and $HC\equiv N-KrF$.¹¹⁵

The nitrogen shielding in comparable groups decreases with increasing electronegativity of the neighbor, or with an

Figure 2 Comparison of nitrogen and carbon shifts

Figure 3 Ranges of nitrogen shifts in compounds with main group elements

increase in the positive charge on the ion. Lower shielding may be observed for terminal atoms in linear groups, as in $\text{MeCN} > \text{N}_2 > \text{NO}^+$, or $\text{MeNC} > \text{CN}^- > \text{CO}$.

Figure 2 shows the comparability of the carbon and the nitrogen shielding in isoelectronic pairs such as CH_4 and NH_4^+ , CO (or CN^-) and NO^+ , or CO_3^{2-} and NO_3^- , even for pairs which are not isostructural such as C_2H_6 and N_2H_4 since the lone-pair excitation energies in hydrazine are rather high. The shielding in comparable compounds decreases from single (e.g. $\text{H}_2\text{N}-\text{NH}_2$) to triple ($\text{N}\equiv\text{N}$) to double bonds ($\text{RN}=\text{NR}$) in nitrogen as in carbon resonance. This is the sequence of decrease in symmetry of the local electronic charge (and increase in the NQCC, as illustrated in Table 4) and of decreasing excitation energies.¹¹⁶

In the $n \rightarrow \pi^*$ excitation, charge circulates from the p component of the lone pair into the π^* orbital. The $n \rightarrow \pi^*$ excitation energies are low for diazenes $\text{RN}=\text{NR}$, particularly in extended conjugated systems as in azo dyes.¹¹⁷ The $n \rightarrow \pi^*$ excitation energies and nitrogen shieldings are particularly low for nitroso compounds RNO and nitrosyls NOX . All three factors in equation (11) are operative: the bent nitrogen carrying a lone pair is highly anisotropic, $\langle r^{-3} \rangle_{2p}$ is large because of the electronegativity of oxygen, ΔE is very low since the π^* LUMO is low (because of the electronegativity of oxygen), and the nitrogen lone pair HOMO is raised by the presence of lone-pair electrons on the oxygen.

When excitation energies are small, linear δ/λ correlations may be observed between the chemical shifts δ and the wavelength λ of the low-energy absorption band in the electronic

Figure 4 Ranges of nitrogen shifts in metal complexes

spectrum. Such correlations are well known for organic and inorganic compounds with $n_N \rightarrow \pi^*$ absorption: for carbonyl compounds $RCHO$ or $RCOR'$ in carbon resonance, and in nitrogen resonance, for nitrosyl compounds NOX and RNO ,¹¹⁸ azo (diazene) compounds $XN=NX$ and $RN=NR$,¹¹⁹ diazo compounds YNN ,¹²⁰ etc. The nitrogen shielding decreases as the $n_N \rightarrow \pi^*$ band moves to longer wavelengths, from the colorless oxo/fluoro compounds NOF , $FNNF$, etc., to the compounds with less electronegative substituents, such as $PhNO$, $t-BuNO$, or $Me_3SiN=NSiMe_3$ which are blue, and the 1,1-diazenes R_2NN which are purple.¹²¹ In $n_N \rightarrow \pi^*$ chromophores, the nitrogen shift δ and $\lambda(n_N \rightarrow \pi^*)$ both increase in the sequence $N=C < N=N < N=O$ of increase in the electronegativity of the partner in the double bond, lowering the π^* relative to the n_N orbital and increasing $\langle r^{-3} \rangle_{2p}$ for the nitrogen.

4.2 Protonation Shifts

Protonation of the singly bonded nitrogen in ammonia or amines deshields the nitrogen by up to 20 ppm. The deshielding is largest in ammonia in which the charge is strongly localized. Because of the relatively small protonation shifts in amines, there are similar shift relationships for amine nitrogen and alkane carbon in corresponding environments, depending on connectivity, although the groups are not isostructural. Amines which are branched at the α -carbon show small increases in nitrogen shielding on protonation.

Since nitrogen is strongly deshielding by $n \rightarrow \pi^*$ circulations, the effects of protonation of nitrogen in a π -bonded system may be large. Protonation of pyridine increases the nitrogen shielding by about 100 ppm, as the lone-pair electrons on nitrogen are strongly stabilized by the formation of a bond to hydrogen. The radial term $\langle r^{-3} \rangle_{2p}$ is not greatly increased by the positive charge, which is delocalized. Large effects may be observed in metal complexes. Protonation of

dinitrogen attached to tungsten to form the (linear) diazenido ligand, and then the hydrazido(2-) ligand, increases the shielding of the β -nitrogen by 135 and then 55 ppm:¹²² $W-N\equiv N \rightarrow W-N=NH \rightarrow W=N-NH_2$. Protonation shifts of 200 ppm are observed for the doubly bent diazenido group $Pt(II)-N=NPh$ to give a hydrazido(1-) ligand, $Pt-NH=NPh$.¹²³

An exception which proves the rule is the deshielding of nitrogen by ca. 100 ppm on protonation of the cyclic anion formed by deprotonation of 2,4,6-trimethylpyridine.¹²⁴

4.3 Nitrogen NMR Criteria of Structure

The relationships illustrated in Figures 2–4 allow some generalizations on the structural determinants of nitrogen shieldings, in advance of more rigorous discussion of the shielding tensor.

1. In groups which may be bent or linear at nitrogen, the nitrogen is deshielded as the bond angle decreases. The deshielding on bending is the greater, the greater the deshielding in the linear group: thus, bent nitrogen in azides is still quite highly shielded.¹²⁵ Deshieldings are greater in aromatic azines and azoles, and may be greater still in triazenes, as in the $(Ts-NNN-Ts)^-$ ion (Ts = tosyl), in which the central nitrogen is deshielded by 286 ppm compared with the central nitrogen in azide ion, NNN^- .¹²⁶ The difference in nitrogen shift is small for linear and bent imido ligands $M=NR$,¹²⁷ but large in diazenido ligands $M-N=N$ which are bent at the ligating nitrogen.¹²⁴ The nitrosyl group shows large deshieldings. The bent nitrogen in the *N*-nitrosamine Me_2NNO is deshielded by 300 ppm compared with the central nitrogen in nitrous oxide, N_2O , and the nitrogen is deshielded further if the group is distorted from planarity.¹²⁸ Deshieldings up to 800 ppm are reported for metal nitrosyls in the bent compared with the linear ligand,¹²⁹ with smaller shieldings for smaller MNO angles.¹³⁰ Reactions which involve the shift of a d-electron pair onto ligating nitrogen, allowing the metal to accept an incoming ligand and the nitrogen to coordinate a Lewis acid, are readily monitored by nitrogen NMR.]
2. In groups which may be pyramidal at nitrogen carrying a lone pair, or flat, with π delocalization of the lone-pair electrons, the nitrogen is deshielded the flatter the group, as noted early on in substituted anilines.^{2,3} Planarity allows $\pi \leftrightarrow \sigma$ paramagnetic circulations of lower energy than $n_N \rightarrow \sigma^*$ circulations in the pyramidal group. In the planar hydrazido(2-) ligand $M=N-NH_2$, the nitrogen shift (ca. -230 ppm¹³¹) shows significant deshielding compared with hydrazines (ca. -320 ppm), being comparable with amide shifts (cf. -265 ppm for formamide).
3. Protonation and deprotonation shifts have considerable diagnostic value in structural studies. Hydrogen bonding to a lone pair on nitrogen leads to smaller shifts in the same sense. Hydrogen bonding of attached hydrogen gives nitrogen shifts in the opposite sense. Tautomeric and other acid-base systems involving nitrogen are thus well studied by nitrogen NMR methods, with the information from the shifts, ^{14}N linewidths, ^{15}N NOE, and couplings.
4. Coordination shifts may be comparable to protonation shifts. Thus, coordination of BH_3 or BMe_3 to ammonia or alkylamines deshields the nitrogen by a small amount, and

coordination to π -bonded nitrogen increases the shielding markedly, as by 74 ppm when pyridine forms $py \cdot BH_3$. Coordination to transition metals is a more complex question (Section 4.5).

4.4 Nitrogen Bonded to Heteroelements

Figures 3 and 4 show high shielding for carbon or nitrogen singly bonded to boron,¹³² silicon, phosphorus,¹³³ etc., or to transition metals in ammine complexes. These elements are less electronegative than nitrogen. Nitrogen is strongly deshielded in singly-bonded compounds with fluoronitrogen compounds by 370 ppm for liquid NF_3 compared with NH_3 , or 290 ppm for NF_4^+ compared with NH_4^+ .²⁸ Because of the extreme electronegativity of fluorine, its effects as a substituent often have diagnostic value, and have been called (per)fluoro effects in photoelectron and electronic spectroscopy.

In a comparison of similar $N-X$ compounds, the nitrogen shift ranges show periodic trends reflecting the inductive effects of the heteroelement. The nitrogen shielding decreases across the row of the heteroelement, e.g. from $B-N$ to $N-O$ and from $Si-N$ to $N-Cl$, with an increase in the electronegativity of X ; and increases down the group of the neighbor, with a decrease in the electronegativity of X , an increase in polarizability and relativistic effects, and with heavy atom neighbors.

Fluoro effects provide extreme examples, as in the σ -fluoro effects already described. These, and π -fluoro effects, are used in photoelectron and electronic spectroscopy for assignments to σ or π orbitals. Fluorination strongly stabilizes the σ -orbital manifold, of which the lone-pair orbital forms part. The stabilization is less for the π -orbital manifold, in part due to repulsion of π electrons by lone-pair electrons on fluorine. Although nitrogen is strongly deshielded in NF_3 and NF_4^+ compared with NH_3 and NH_4^+ , nitrogen shielding is significantly increased on fluorination of azabenzenes and other planar species (cf. NOF , NO_2F , and N_2F_2).¹³⁴ π -Chloro effects are similar, and smaller.

4.5 Coordination Shifts in Metal Complexes

Coordination shifts from the free ligand to the complex are illustrated by a comparison of Figures 3 and 4, and in Figure 4 itself, since the shift for the free ligand is indicated.

Coordination shifts are usually small in the higher shielding ranges, and smaller for p-block than for d-block metals. On coordination to a transition metal, the nonbonding electrons on nitrogen are stabilized by bond formation, this tending to increase the nitrogen shielding, but low-lying orbitals may then become available to the paramagnetic circulation on ligating nitrogen.

Nitrogen NMR is a criterion of the mode of coordination of ambidentate ligands. Nitrogen is more shielded in $M-NCS$ than in $MSCN$ or in the free NCS^- ion.¹³⁵ Similarly, in the covalent azides $XN_\alpha N_\beta N_\gamma$, N_α is the most highly shielded nitrogen with N_β being buffered from the effects of coordination.¹³⁶

Relatively low shielding is observed for ligating nitrogen in doubly bonded groups such as hydrazide(2-), $M=N-NH_2$, and for π -acceptor ligands such as $NCMe$, N_2 , NO , NS , etc.

The importance of the ligand field splitting to the nitrogen shift is shown by the periodic dependence on the transition metal and by *trans* effects.¹³⁷ These influences are magnified if nitrogen is close to the metal, as in nitrido complexes,¹³³ and for bent or bridging nitrido or nitrosyl ligands.

Trans influences may parallel substituent effects in arenes, such as the increase in nitrogen shielding in anilines, pyridines, and benzonitriles with *para*-substituents which are π donors (and the deshielding if nitrogen with π acceptors). In linear nitrosyl or diazenido complexes, the shielding of ligating nitrogen is increased by *trans*-donors such as OH, and decreased by *trans*-acceptors such as CN or NCMe. The strength of binding of the *trans*-ligand is also significant, since the $d\sigma$ -orbital splitting is larger with softer ligands for metals in low oxidation states. Such correlations include other physical properties such as IR stretching frequencies, reflecting back-bonding to acceptor ligands such as N₂, or redox potentials.

Interest in nitrogen fixation processes has stimulated the study of the dinitrogen ligand in complexes of molybdenum and related metals, and of ligands on the reduction pathway, diazenido, hydrazido, hydrazinium, imido, etc. Nitrogen NMR spectroscopy can usefully distinguish terminal and bridging, or linear and bent ligands, and monitor protonation reactions.

5 NITROGEN SHIELDING TENSORS

More rigorous consideration of the factors determining nitrogen NMR shifts requires a knowledge of the shielding tensor, preferably in conjunction with theoretical calculations. Shielding tensor components have been measured for a number of nitrogen bond types, including ligands in metal complexes. There has been much interest in groups of biological importance, in peptide or imino links for example, in which nitrogen shielding tensors give useful information on the effects of protonation and hydrogen bonding. Other articles discussing nitrogen shielding tensors in biomolecules are given at the end of this section.

Nitrogen tensors resemble those for carbon or phosphorus in isoelectronic and isostructural locations, with scaling by the respective radial factors $\langle r^{-3} \rangle_{np}$ which are in a 2:1 ratio for nitrogen and carbon, as discussed in Section 4.^{109,110} Nitrogen shielding patterns are more closely related to those of phosphorus than of carbon, since the nitrogen and phosphorus valencies are closer, as are the scaling factors, since the ratio of $\langle r^{-3} \rangle_{2p}(\text{N})$ to $\langle r^{-3} \rangle_{3p}(\text{P})$ is 1:0.7.

A major factor for many nitrogen tensors is the presence of lone pair (n_N) electrons on the nitrogen which are strongly directional. The lone-pair axial direction then determines the principal axis system, and major deshieldings are observed for axes which mix n_N and π^* orbitals, following the arguments given in Section 4. Similarly, the nitrogen shielding tensor is a criterion for the bending of two-coordinate nitrogen and the flattening of three-coordinate nitrogen. Tensor measurements, combined with theoretical studies, can frequently throw light on the nature of the bonding.

5.1 Experimental Techniques

The spin-rotation interaction, measured as fine structure in the microwave spectra of gases, has given ¹⁴N tensor

information for NH₃,¹⁶ N₂O,¹⁴² HCN,¹⁴³ and PN¹⁴⁴ (Tables 5 and 6). Tensor measurements have been made on oriented single crystals of glycylglycine · HCl · H₂O^{145,146} and L-histidine · HCl · H₂O in ¹⁵N resonance, and some nitrates in ¹⁴N resonance (Table 7). Most measurements, however, are made on powdered material by ¹⁵N MAS or CP MAS techniques, and/or powder lineshape analysis on a static sample. Some anisotropies have been measured in liquid crystals (MeNC, MeCN, N₂O) and some by relaxation methods (PhNO₂, pyridine).

For some molecules or groups, the orientation of the shielding tensor in the molecular frame is obvious from the chemical structure, and for some it has been established by single crystal measurements. For some others, the orientation has been determined by concurrent measurement of dipolar interaction between ¹⁴N or ¹⁵N with ¹H, ²H, ¹³C, ³¹P, or other nuclei.^{140,145,147} Theoretical calculations, also, may help in the assignment of the axial directions.

Tables 5–7 give the principal components as absolute shieldings σ , with $\sigma_{33} > \sigma_{22} > \sigma_{11}$, and $\sigma_{\text{iso}} = \sigma_{\text{tr}} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$. The shieldings are obtained from the chemical shift, δ , with neat liquid nitromethane as standard, according to equation (1), using the absolute scale¹⁹ based on the spin-rotation measurement for NH₃, according to which nitrogen in neat liquid nitromethane has shielding $\sigma = -135.8$:

$$\sigma = -135.8 - \delta(\text{MeNO}_2) \quad (12)$$

Some authors use a liquid ammonia standard, for which the nitrogen shieldings are 244.6 ppm at ambient temperatures and 240.6 at -50°C .¹⁷ Some others use solid NH₄Cl as the reference material, with $\sigma(\text{N}) = 202.5$.

The tensor properties given in Tables 5–7 are the span $\Omega = \sigma_{33} - \sigma_{11}$ and the skew $\kappa = 3(\sigma_{22} - \sigma_{\text{iso}})/\Omega$.^{148,149} For axial tensors, $\Omega = \sigma_{\parallel} - \sigma_{\perp}$ and $\kappa = \pm 1$. The parameters Ω and κ avoid ambiguities that have arisen with the traditional parameters,¹⁵⁰ the shielding anisotropy $\Delta\sigma$ and asymmetry η . For these, the ordering of the σ_{11} , σ_{22} , and σ_{33} axes depends on the ordering of the absolute values of the differences of the tensor elements from σ_{iso} . Some authors have followed the ‘traditional’ order σ_{33} , σ_{22} , and σ_{11} ,¹⁴⁵ while some use the numerical order σ_{33} , σ_{22} , and σ_{11} . In any case, the σ_{33} and σ_{11} axes have to be interchanged for those members of an extended series of compounds which have $\sigma_{22} < \sigma_{\text{iso}}$, as compared with those with $\sigma_{22} > \sigma_{\text{iso}}$. Such series include metal nitrosyls in nitrogen resonance, as described in Section 5.5, or organic carbonyl compounds in carbon resonance.¹⁵¹

Several authors¹⁵² have used the relative magnitudes of the principal components to define the axes as here, rather than relative magnitudes of the absolute values of the differences from σ_{iso} as in the ‘traditional’ definition. The use of the skew parameter κ rather than the asymmetry parameter η preserves sign information, since on the traditional definition $0 \leq \eta \leq 1$ and $\eta = 0$ for axial symmetry whether $\sigma_{\parallel}$ is greater or less than $\sigma_{\perp}$. The skew κ , however, is +1 for $\sigma_{\parallel} > \sigma_{\perp}$ and –1 for $\sigma_{\parallel} < \sigma_{\perp}$.

5.2 Singly Bonded Nitrogen

Shielding tensors are given in Table 5 for nitrogen in ammonia and some derivatives. Although distortion of an oxyanion such as nitrate by hydrogen bonding to the

^a Assumes glycine zwitterion reference has $\delta(\text{N})$ −350 ppm.

ammonium ion has been observed in the nitrogen shielding tensor, the ammonium cation gives a symmetric tensor, as for near-tetrahedral symmetry and reorientational motion such as the switching in NH_4Cl (Section 3).

The shielding tensor for ammonia is unusual in having $\sigma_{\parallel} < \sigma_{\perp}$ ($\kappa = 1$) and a small span, 40.3 ppm.¹⁶ Ammonia is unusual also in the substantial *decrease* in the nitrogen shielding on protonation, as discussed in Section 4. In ammonium salts, the NH_4^+ nitrogen shielding decreases with a decrease in strength of the hydrogen bond to the counteranion (i.e., with a decrease in the electronegativity of the anion), increasing the positive charge on nitrogen.^{153,154} The deshielding is related to contraction of the 2p N orbitals from NH_3 to $\text{NH}_3 \cdots \text{H}^+$, with a strongly hydrogen-bonding anion, and then to NH_4^+ , as the counterion hydrogen bonds more weakly.

Much smaller deshieldings are observed on the protonation of amines, in which cationic charge is less localized on the nitrogen. R-NH_3^+ tensors, of which a number have been measured in biomolecules such as histidine or glycine, have a very small span, about 10 ppm.

There is little change in the NH_3 isotropic shift on formation of ammine ligands in *cis*- $[\text{Pt}^{15}\text{NH}_3)_2(\text{SCN})_2]$, with weak bonding to the metal. There is some increase in span of the NH_3 tensor, but a considerable decrease in the skew, in this planar complex. The σ_{33} component is sensitive to a change in location in the crystal.¹⁵⁵

Combined shielding tensor and dipolar shift measurements have been used to characterize NH protons and measure the bond distances in polycrystalline and amorphous solids of biological importance, in ^{14}N ¹⁵⁶ and in ^{15}N ¹⁵⁷ resonance. Protonated imine nitrogen is discussed under the heading of the parent compound.

5.3 Nitrogen in Linear Groups

The principal components of nitrogen shielding tensors for linear systems are given in Table 6. Maximal shielding is observed for the C_{∞} axis with its largely diamagnetic circulation. Most values of the parallel shielding $\sigma_{\parallel}$ are in the range 300–370 ppm, resembling the (diamagnetic) shielding of atomic nitrogen, 325 ppm.¹⁵⁸

The parallel shielding, 350 ppm in MeCN ,¹⁵⁹ decreases by 80–100 ppm when the π electrons can delocalize into an aromatic ring, as in the iminophosphenium cation¹⁶⁰ and benzonitriles.¹⁶¹ Interesting σ -inductive and π -conjugative effects of a 4-substituent in the benzene ring on the cyano-nitrogen shielding tensor have been monitored for benzonitriles $4\text{-Y-C}_6\text{H}_4\text{-C}\equiv\text{N}$ with $\text{Y} = \text{OMe}, \text{NMe}_2, \text{NO}_2, \text{CN}, \text{Cl}, \text{Br}, \text{F}, \text{Me}, \text{CMe}_3$, and NMe_3^+ . Some of the largest changes in tensor components relative to $\text{Y} = \text{Me}$ are produced by a positively charged substituent NMe_3^+ , which decreases σ_{33} in the $\text{C}\equiv\text{N}$ by 11 ppm (and σ_{11} and σ_{22} by 7 and 16 ppm, respectively). Similarly the parallel shieldings in dinitrogen $\text{N}\equiv\text{N}$ ¹⁶² are reduced by 51 and 13 ppm on coordination to molybdenum.

The perpendicular tensor components arise from $\sigma \leftrightarrow \pi$ (i.e., $\sigma \rightarrow \pi^*$ and $\pi \rightarrow \sigma^*$) circulations, and for terminal nitrogen from $\text{n}_\text{N} \rightarrow \pi^*$ circulations also. The separation of the σ_{11} and σ_{22} components by around 30 ppm in the benzonitriles and iminophosphenium ion reflects conjugation with the aromatic ring. In the benzonitriles the separation is largest (41 ppm) with the π -donor Me_2N as the 4-substituent.

For terminal nitrogen in the linear groups the perpendicular shielding ($\sigma_{\perp}$) is highest in NNO and lowest for PN : the latter has the longest bond (so orbital splittings are smaller) and phosphorus is the least electronegative partner. For N_2O , ab initio calculations using the LORG method¹⁶³ show comparable (major) contributions to σ_{p} for the terminal nitrogen from its lone pair and the NN bond, and for the central nitrogen from the NN and NO bonds.

For two-coordinate nitrogen, the perpendicular shielding decreases from MeNC ¹⁶⁴ to ArNP^+ and to $[\text{Mo}(\text{dppe})_2(^{15}\text{N}_2)_2]$,¹⁶⁵ as the orbital splittings decrease.

5.4 Nitrogen in Planar Systems

Principal values for nitrogen tensors in planar systems are given in Table 7. The highest shielding and a small span are observed for three-coordinate nitrogen bound only to carbon and hydrogen, in amides or peptides, azinium nitrogen in the five-membered rings in tryptophan, and L-histidine $\cdot \text{HCl} \cdot \text{H}_2\text{O}$ and iminium groups.

5.4.1 Peptides and Amides

Table 7 shows the similarities of the components in an amide, asparagine,¹⁶⁶ in which the σ_{33} axis bisects the NH_2 group, in Nylon-6,¹⁶⁷ and in peptides.^{139–168} Concurrent observations of $^{13}\text{C}^{15}\text{N}$ and $^{15}\text{N}^1\text{H}$ dipolar interactions in L-(1- ^{13}C)alanyl-L-(^{15}N)alanine confirmed earlier conclusions on the orientation of the nitrogen tensor.¹⁴² The axis of lowest shielding σ_{11} is in the amide plane perpendicular to the CN bond, allowing relatively low-energy $\text{CN } \sigma \leftrightarrow \pi$ circulations. Unusually (in contrast to carbon tensors in peptides, and to carbon and nitrogen tensors in aromatic and other delocalized systems), the high-shielding axis σ_{33} is in-plane in the CN bond direction; the intermediate axis σ_{22} is perpendicular to the plane. These directions are approximate, varying somewhat in different peptides. In glycylglycine and related peptide links, there is, accidentally, near-axial symmetry, with $\kappa \approx +1$, and the σ_{11} axis is at 99° to the CN bond.

The σ_{11} component is the least variable because of constancy of the CN bond, although sensitive to the geometry of the hydrogen bonding, the σ_{11} axis being nearest to the $\text{N-H} \cdots \text{O}$ direction. The σ_{11} axis is smaller in an α -helix than in a β -sheet, and is sensitive also to the handedness of the helix. The out-of-plane component σ_{22} reflects the conformation and secondary structure, being larger in a β -sheet than in an α -helix.¹⁶⁹ The σ_{22} component is unusually low and σ_{33} unusually high ($\kappa = -0.3$) in the link to proline, in which the nitrogen is in a saturated five-membered ring, although the alanylalanine isotropic shift is maintained in alanylproline.¹⁷⁰ The importance of lattice effects is shown by differences of isotropic shifts in solution.

5.4.2 Azines, Azinium

Despite the chemical importance of aromatic azines, few of their nitrogen tensors have been studied to date. Table 7 includes ranges of principal components observed for protonated nitrogen in five-membered rings of biological interest, in tryptophan^{159,171} and in histidine.¹⁵⁹ These components are comparable to the values for pyridine.¹⁷² In delocalized ($\text{p}\pi$)

systems, the out-of-plane axis shows the highest shielding (σ_{33}) in carbon resonance, depending on the relatively high-energy $\sigma \rightarrow \sigma^*$ excitations in the plane. This is borne out in nitrogen resonance, as in the protonated imidazole ring in histidine hydrochloride: the σ_{33} axis is almost perpendicular to the ring and the σ_{11} axis almost along the NH bond. Similar components are observed for tryptophan, studied as the hydrochloride, and in vivo in a bacteriophage that orients in the magnetic field.

Comparison with pyridine shows the major increases in σ_{11} and σ_{22} on protonation. In pyridine, the σ_{11} axis is tangential to the ring, mixing n_N and π^* orbitals, and the σ_{22} axis radial, this shielding being mediated by $\sigma \leftrightarrow \pi$ circulations. The value of σ_{22} for pyridine resembles that of $\sigma_{\perp}$ in MeCN, rather than MeNC (Table 6).

5.4.3 Planar Systems with CN, NN, NP, and NO Bonds

The cyano and phosphonium groups in ArCN and ArN⁺P can be described as planar, since conjugation with the aromatic system removes the axial symmetry of the CN and PN groups, although these bonds are triple and form the σ_{33} axis.

In the compounds with bent two-coordinate nitrogen, benzyldeneaniline,¹⁷³ (*E*)-acetophenone oxime,¹⁷⁴ *trans*-azobenzene,¹⁷⁵ and 4-dimethylaminonitrosobenzene,¹⁷² dipolar chemical shift measurements support the σ_{22} direction as bisecting the angle at nitrogen (effectively along the lone-pair axis). The σ_{11} axis is that of the $n_N \rightarrow \pi^*$ circulation. The nitrogen tensors show that the σ_{11} component in the planar groups becomes more strongly negative as the π^* LUMOs come down in energy relative to the n_N orbital, with increasing electronegativity of the partner in the double bond from C=N to N=N and to N=O. Very low shieldings are $\sigma_{11} = -789$ ppm for azobenzene (which is red-orange, with $n_N \rightarrow \pi^*$ absorption at 448 nm) and -1457 ppm for 1,4-dimethylaminonitrosobenzene¹⁷⁴ which is green.

In *trans*-azobenzene there are two molecular sites, differing in the span (925 and 880 ppm) and skew (0.392 and 0.325), while the isotropic shift is maintained. The azo group (CNNC) is effectively planar and centrosymmetric in both sites with the same N=N bond length, but the torsion angles NNCC are significantly different, 17° and <10°. (The low barrier to twisting of the phenyl group is shown by the torsion angle of 30° observed in the gas phase by electron diffraction.)

The nitrate ion is characterized by a small span.^{176,177} The σ_{22} component is less negative in nitrobenzene because of the smaller paramagnetic contribution of the CN bond, and more negative when there is a lone pair on nitrogen in the plane as in the bent nitroso group in Me₂NC₆H₄NO. The nitrite ion is intermediate as expected.¹⁷⁸

A sizeable (σ_{11}) deshielding is associated with the $n_N \rightarrow \pi^*$ circulation in bent nitrosyl groups, and to a lesser extent in NO₂[−] for which LORG calculations¹⁷⁶ show that the contribution to $\sigma_{P_{iso}}$ of the n_N electrons on the symmetry axis exceeds that of the NO bonds. In contrast is the high shielding in the nitroso dimer PhN(O)N(O)Ph, which is a diazene bis-*N*-oxide: the σ_{11} and σ_{22} values match those in nitrobenzene, and σ_{33} matches $\sigma_{\perp}$ in the nitrate ion.¹⁷⁹

The effects of protonation of π -bonded nitrogen, and of variations in the strength of hydrogen bonding to a counterion, have been studied in the Schiff base (aldimine) retinylidene-Buⁿ-(¹⁵N)imine, RB. This models the light-harvesting membrane protein bacteriorhodopsin (bR) which was measured

with selective ¹⁵N,¹³C-enrichment. Protonation of bR with a strong acid (HCl) increases σ_{11} by 327 ppm and σ_{22} by 115 ppm (Table 7). From HCl to HBr to HI and to weak organic acids (carboxylic acids or phenols), σ_{11} and σ_{22} show small increases with strengthening of the N–H⁺ bond (σ_{11} and σ_{22} being linearly related) while σ_{33} is little changed. The values for dark-adapted bR resemble those of RBH⁺ when very weakly hydrogen bonded.¹⁸⁰

The ¹⁵N and ¹³C studies demonstrate the major contribution of the counterion to the opsin shift in the photocycle. Color changes in the protein with pH correlate with changes in the ¹⁵N shielding, which increases as the neutral purple membrane (568 nm) becomes the acid blue membrane (600 nm), reverting with the change to the acid purple membrane (565 nm); the weak hydrogen bond in the protein weakens in the blue form. The opsin-induced red shift, therefore, arises from interaction of an electronegative group in the protein with the Schiff base end of the chromophore, *cis*–*trans* isomerization being excluded by the comparison with the 13-*cis*,15-*syn*-bR₅₄₈ tensor.

5.5 Linear and Bent Nitrosyls in Metal Complexes

The nitrogen shielding tensor is a useful criterion for the bending of the nitrosyl ligand, and many of the nitrosyls studied are unstable in solution. In five-coordinate {MNO}⁸ complexes (i.e., with eight (d + n) electrons), the metal may have a trigonal pyramidal coordination sphere (d⁸) with the nitrosyl linear (NO⁺), or else a square-pyramidal coordination sphere (d⁶) with bent apical nitrosyl (NO[−]), and similarly for the diazenido ligand (N=NR⁺ and N=NR[−]). The first measurement of a nitrogen tensor in a metal complex was of [RuCl(¹⁵NO)₂(PPh₃)₂][BF₄],²³ which has one linear and one bent nitrosyl in the solid state and shows fast bent–linear fluxionality in solution.²⁴

Table 8 lists the nitrogen tensor components for linear nitrosyl ligands, which may be compared with those of NNO and the bent nitrosyl in [RuCl(¹⁵NO)₂(PPh₃)₂]⁺ in Table 9. In the linear ligand, as in [Fe(CO)₃(¹⁵NO)][−],¹⁸¹ the $\sigma_{\parallel}$ values are significantly more negative than is expected for the free ligand NO⁺. This reflects greater back-bonding to the nitrosyl compared with the carbonyl ligand, which is a useful model with many ¹³C tensors having been measured.¹³⁸ The perpendicular components in the nitrosyls are somewhat more negative than in NNO, and more negative in a bis-nitrosyl than in a mononitrosyl, for the same metal. Bis-nitrosyls are usually *cis* and the neighboring nitrosyls interact, to bend slightly. [Fe(NO)₂ (cystine)] is an example of a compound for which the nitrogen shielding tensor has given the structure: the solid is amorphous and insoluble, but the nitrogen tensors clearly show the nitrosyls to be linear and probably *cis*.¹⁸²

The ruthenium complex with one bent and one linear nitrosyl shows that bending of the nitrosyl makes a large paramagnetic contribution to σ_{11} and a significant contribution also to σ_{33} . These effects can be seen to some degree in the bis-nitrosyls in Table 8, the adjacent linear ligands interacting to produce a small degree of bending.

Table 9 gives the tensor properties of bent nitrosyl ligands, and Figure 5 shows the structures of the complexes.^{182–184} In some complexes the planarity of the basal ligand is maintained by chemical bonding or strong hydrogen bonding. In the

^aBridging NO.

others, the nitrogen tensor components are a useful proof of structure since all have the pyramidal structure, but not all the bis-chelate compounds are constrained to coplanarity. An example is the $[\text{Co}(\text{NO})(\text{rsal})_2]$ series, of which the parent complexes $[\text{Co}(\text{rsal})_2]$ have tetrahedral coordination. For $[\text{CoCl}_2(^{15}\text{NO})(\text{PPh}_3)_2]$, which is fluxional in solution, the tensor properties show the nitrosyl to be bent in the solid.

All three tensor components for bent nitrosyls show significant deshielding compared with those in linear nitrosyls. The σ_{11} values are strongly negative and very variable. The bridging nitrosyl in $[\text{Ru}_3(\text{CO})_{16}(\mu_2\text{-NO})]^-$ shows a relatively high σ_{11} shielding as the nitrogen is now three-coordinate, Ru_2NO ; the σ_{33} shielding is unexpectedly high.

The apical nitrosyls show a remarkable variation in the span and skew, while the isotropic shift δ is maintained at 680–780 ppm, except for higher shielding with S_4 ligation of cobalt. All components reflect significant mixing of the nitrogen and the cobalt paramagnetic circulations (more precisely, the out-of-plane components of the ligand field circulations deshielding cobalt), as observed in solution studies showing some correlation of ^{15}N and ^{59}Co shifts.¹²⁹

Because of the large effects of relatively small changes in small excitation energies, sensitivity may be expected to the internal MNO geometry and to the conformation of the nitrosyl relative to the ligands in the basal plane. The ligand field

is also sensitive to the location of cobalt (usually above the plane), to the ligation, and to the bite of the chelate ligands. The nitrosyl oxygen may lie over a gap between two chelate ligands as in $[\text{Co}(\text{NO})(\text{ketox})_2]$ and $[\text{Co}(\text{NO})(\text{esal})_2]$, or over an electron acceptor such as a phosphine. It lies over the ethylene bridge in $[\text{Co}(\text{NO})(7\text{-mesalen})]$ and $[\text{Co}(\text{NO})(\text{salen})]$, over a linear nitrosyl in $[\text{RuCl}(^{15}\text{NO})_2(\text{PPh}_3)_2]^+$, over sulfur in $[\text{Co}(\text{NO})(\text{S}_2\text{CNMe}_2)_2]$, over oxygen in $[\text{Co}(\text{NO})(\text{acacen})]$, and over nitrogen in $[\text{Co}(\text{NO})(\text{benacen})]$.

The remarkable variation of the tensor components in Table 9 may involve the effects of the conformation of the nitrosyl relative to the ligand field of the coligands in the plane, and the small barrier to rotation of the nitrosyl which is disordered in many of the crystal structures. Torsional variation could account for compensatory effects in the tensor components, with σ_{22} and σ_{33} decreasing as σ_{11} increases, decreasing the span while maintaining the isotropic shift.

A low torsional barrier and the sensitivity of the projecting nitrosyl to intermolecular forces are shown by the unusual nitrogen tensors observed for $[\text{Co}(^{15}\text{NO})(\text{TPP})]$ at ambient temperatures, which demonstrate swinging or spinning of the nitrosyl in the solid state.¹⁸⁴ The isotropic shift is that of a bent nitrosyl, but from room temperature down to 220 K the tensor shows axial symmetry ($\kappa = 1$) and a small span, 242 ppm. The full span of 1655 ppm and nonaxial symmetry appeared when

Figure 5 Structures of complexes with a bent apical nitrosyl ligand

the sample was cooled to 200 K, with little change in isotropic shift.

No intermediate rate behavior was observed and differential scanning calorimetry showed a phase transition in the solid at 206.7 K with $\Delta H = 649 \text{ J mol}^{-1}$. The lattice presumably relaxes at this temperature, allowing the nitrosyl to revolve about the C_4 axis at higher temperatures. A CoNO angle of 127° calculated from the tensor measurements agrees with the value of $\leq 128.5^\circ$ estimated from the X-ray diffraction study at ambient temperatures.¹⁸⁵ This showed a fourfold disorder of the nitrosyl depicted in a many-headed 'hydra' diagram, the oxygen lying in the gap between two porphyrin nitrogens. This picture, therefore, is that of a swinging nitrosyl.

5.6 Theoretical Calculations of Nitrogen Shielding Tensors

Several ab initio methods are now being used with some success for the calculation of shielding tensors,¹⁴⁹ including the local-origin methods IGLO¹⁸⁶ and LORG.¹⁸⁷ Agreement with experiment is good for singly bonded molecules with high electronic excitation energies. It is less good when excitation energies are low, and for species with multiple bonds and lone pairs on the nucleus in question. This presents hazards in nitrogen studies, particularly in groups containing oxygen.

IGLO calculations¹⁸⁸ of nitrogen shieldings for a range of compounds have been analyzed in terms of the contributions from bonding electrons and lone pairs. The calculations show very small deshielding in NH₃, and greater deshielding

on substitution of H by Me, then NH₂, OH, or F, with strong effects on the lone-pair contribution. The Cl and Ph groups behave as weakly electronegative substituents. Strong deshielding is found when the nitrogen is doubly bonded, with some exaggeration of the paramagnetic effect in the calculation. In aromatic azines, the calculations reflect the deshielding observed from pyrrole (with no $n \rightarrow \pi^*$ state) to pyridine and to pyridazine (with two adjacent nitrogens).

In molecules with low excitation energies the inclusion of electron correlation to second order, as in the SOLO (second-order LORG) method,¹⁸⁹ produces considerable improvement, as in a study of nitrite and nitrate ions.¹⁷⁸ There is further improvement with the inclusion of six surrounding cations for nitrite ion. The decrease in shielding with lengthening of the NO bonds, or, for nitrite, with an increase in the bond angle, shows that vibrational corrections are also significant.

6 PATTERNS OF NITROGEN SPIN-SPIN COUPLINGS

Figures 6–8 give ranges of one-bond J couplings between ¹⁵N, ¹H, and ¹³C in functional groups. Couplings to nitrogen are more commonly measured in ¹⁵N than in ¹⁴N resonance because of ¹⁴N line broadening by quadrupolar relaxation. A large number of ¹⁴N couplings have been measured, however, under favorable conditions of high local electronic symmetry and short correlation times (Section 3.2). All four ¹⁴N couplings could be measured with accuracy in the linear cation $\text{RC}\equiv\text{N}^+\text{XeF}^+$.¹¹⁴ More measurements of ¹⁴N and other quadrupolar nuclei, such as the two ¹⁴N¹⁷O couplings measured in N₂O, are expected with the growing use of supercritical fluids.¹⁰⁵

Values of $J(^{14}\text{N}, \text{X})$ are 30% smaller than $J(^{15}\text{N}, \text{X})$ values and opposite in sign, following the respective values of the magnetogyric ratios γ for ¹⁴N and ¹⁵N, as shown in equation (13):

$$-^n J(^{15}\text{N}, \text{X}) = 1.403 ^n J(^{14}\text{N}, \text{X}) = ^n K(\text{N}, \text{X}) \times h\gamma_{\text{N}}\gamma_{\text{X}}/4\pi^2 \quad (13)$$

Here K is the reduced coupling constant, which is independent of the nucleus, and n is the number of bonds through which the nuclei are coupled. The quantity J is in Hz and K is in $\text{N A}^{-2} \text{ m}^{-3}$. Couplings to nitrogen are relatively small since the γ values are rather small. Couplings producing a 1:1 doublet in ¹⁵N resonance produce a 1:1:1 triplet in ¹⁴N resonance because of the three combinations of orientations for a nucleus with $I = 1$.

Figure 6 shows that $^1J(\text{N}, \text{H})$ values are negative, becoming more negative with increasing s character in the N–H bonding orbital, from sp^3 hybridization of the nitrogen as in NH₄⁺ or amines, to sp^2 as in the pyridinium ion pyH^+ , and to sp as in the nitrilium ion $\text{RC}\equiv\text{NH}^+$. Linear equations have been given which relate the coupling to the percentage s character in the nitrogen orbital.^{197–199} These equations, and a corresponding equation relating $^1K(\text{C}, \text{N})$ to the product of the percentage s character in the nitrogen and carbon orbitals,¹⁹⁷ fail when there are lone pairs with s character on one or both of the coupled nuclei, and may fail in the presence of multiple bonding.

Values of $^1J(\text{N}, \text{H})$ are reduced significantly in absolute magnitude by the presence of (s -type) lone pair electron density on nitrogen. The smallest couplings involve bent nitrogen in ketimines $\text{R}_2\text{C}=\text{NH}$ or diazenides $\text{M}-\text{N}=\text{NH}$,

Figure 6 Ranges of $^1J(^{15}\text{N}, ^1\text{H})$ values

and those for amines or ammonia are small. Similarly, $^1J(\text{N}, \text{H})$ values increase significantly in magnitude with the loss of lone pair electron density on nitrogen by coordination, delocalization (as in aniline), or protonation. They also increase with hydrogen bonding of the nitrogen, and may be solvent dependent. NH couplings may be lost through chemical exchange, and rigorous purification may be needed in order to observe them.

Couplings are increased in magnitude regardless of sign by the presence of more electronegative substituents on a coupled nucleus. Values of $^1J(\text{N}, \text{H})$ are quite large in the $-\text{C}(\text{O})\text{NH}-$ link, present in peptides, amides, lactams, ureas, and Nylons. The values are larger if the proton is *trans* to oxygen but decrease with a departure from planarity at the nitrogen, with the development of a lone pair.

Signs reported for $^1J(^{15}\text{N}, ^{13}\text{C})$ are also normally negative, with some exceptional small positive values which change sign and increase in absolute magnitude on protonation. In pyridine $^1J(^{15}\text{N}, ^{13}\text{C})$ is +0.6 Hz, changing to -11.7 Hz on protonation and to -15.2 Hz in pyridine *N*-oxide.²⁰⁰ Figure 7 shows that $^1J(^{15}\text{N}, ^{13}\text{C})$ values become more negative from azomethines $\text{R}_2^{13}\text{C}=\text{N}^\text{R}$, with a lone pair on the nitrogen, to amines, and to ynamines $\text{RC}\equiv^{13}\text{C}-^{15}\text{NR}'_2$, in which there is no lone pair on the nitrogen. Such changes may thus be stereochemically diagnostic. In oximes $\text{R}_2\text{C}=\text{NOH}$, in which the nitrogen is pyramidal, the *Z* form is flatter than the *E* form thus reducing *cis* repulsions and, as expected, $^1J(^{15}\text{N}, \text{C})$ is more negative

for the *Z* than for the *E* form. Values of $^1J(^{15}\text{N}, \text{C})$ are quite large in magnitude for pyrroles, in which the nitrogen 'lone pair' is of the p type.

Signs reported for $^1J(^{15}\text{N}, ^{15}\text{N})$ couplings are negative, but many are still unknown so the values in Figure 8 have been plotted regardless of sign. Values of $^1J(^{15}\text{N}, ^{15}\text{N})$ are generally small in magnitude when terminal nitrogen is involved, as in diazo compounds R_2N_2 , N_2O , or dinitrogen ligands. Similarly in azides $\text{RN}_\alpha\text{N}_\beta\text{N}_\gamma$, which are bent at N_α , $^1J(^{15}\text{N}, ^{15}\text{N})$ couplings are much smaller for $\text{N}_\beta\text{N}_\gamma$ than for $\text{N}_\alpha\text{N}_\beta$. The couplings are very small, around 1 Hz, in arene-diazonium compounds ArNN^+ . Many of these values are the result of complex effects of lone pairs and multiple bonds. Somewhat larger values are observed when the nitrogen is bonded to oxygen.²⁰¹

Geminal couplings $^2J(^{15}\text{N}, \text{H})$ and $^2J(^{15}\text{N}, \text{C})$ are usually negative and relatively small. They become more negative if the nitrogen carries a *cis* or proximate lone pair, the more so if this lies in the NXH or NXC plane. Thus $^2J(^{15}\text{N}, \text{H})$ is -3 Hz in pyH^+ but -11 Hz in pyridine. Such values are diagnostic of the geometry, and of protonation or coordination of the nitrogen. Couplings of the type $^2J(^{15}\text{N}, ^{15}\text{N})$, as observed in nucleotides for example, show similar lone-pair effects. Values of $^3J(^{15}\text{N}, \text{H})$ also are increased in magnitude by a *cis* or proximate lone pair on the nitrogen as in oximes, and the magnitude increases with protonation of the nitrogen as

Figure 7 Ranges of $^1J(^{13}\text{C}, ^{15}\text{N})$ values

in pyridine. Values of $^3J(^{15}\text{N}, \text{C}, \text{C}, \text{H})$ often show a Karplus-type dependence on the dihedral angles, and are of use in conformational studies of peptides in which the 3J values may be larger than 2J values of similar type.²⁰²

6.1 Contact, Orbital, and Spin–Dipolar Contributions to the Coupling^{190, 194, 203–206}

Nitrogen couplings are sensitive to the s,p character of the bonding and to the presence and orientation of a lone pair with s character on the nitrogen, because the Fermi contact interaction of s electrons with the nucleus is usually the most important contribution to the coupling. The coupling patterns are usefully interpreted by means of the Dirac vector model²⁰⁷ of the contact interaction (even though this model is incomplete, and sometimes misleading). Electrons in a bonding pair with antiparallel spins $\alpha\beta$ correlate their motions so that if the α spin is near one nucleus the β spin is near the other. For a nucleus with positive γ , the electron–nuclear configuration is more stable when the spins are antiparallel since $\gamma\epsilon$ is negative. The values of $^1J(\text{X}, \text{Y})$, therefore, are

normally positive, the difference hJ between the energy states with antiparallel and parallel spins being positive by definition. Corresponding values for $^1J(^{15}\text{N}, \text{Y})$ are negative since $\gamma(^{15}\text{N})$ is negative. The coupling increases in absolute magnitude with an increase in s character in the orbitals forming the bond between the coupled nuclei. Similarly, couplings are increased by the presence of more electronegative substituents on a coupled nucleus, since these demand greater p character, leaving more s character in the bond which is the coupling pathway.

Lone pair electron density on either or both of the coupled nuclei alters this picture. Figure 8 shows that if one of the coupled nuclei carries a lone pair, $^1J(\text{N}, \text{C})$ diminishes in absolute magnitude by an amount that increases with the s character of the lone pair, e.g. from RNH_2 , sp^3 , to pyridine, sp^2 (though not to nitriles RCN , sp). As demonstrated in calculations of C–N and N–N couplings, the contribution to the Fermi contact term J^{fc} from the lone pair electrons is opposite in sign to that of the bonding electrons, since the nonbonding MO is antibonding with respect to the coupling pathway. Furthermore, the lone-pair contribution may be quite large, since the energy denominator is small for nonbonding

Figure 8 Ranges of $^1J(^{15}\text{N}, ^{15}\text{N})$ values

electrons. The most important energy term is that of the lowest singlet–triplet excitation, unpairing the electrons.

The changes in sign of $^1J(^{15}\text{N}, \text{C})$ in Figure 8 can be understood in these terms. Thus, $^1J(^{15}\text{N}, \text{C})$, which is commonly negative, becomes less negative and may become positive when the nitrogen carries a lone pair as in pyridine or *cis*-diazenes $\text{R}-\text{N}=\text{N}-\text{R}$. The value of $^1J(^{15}\text{N}, \text{C})$ becomes negative again if the nitrogen is protonated.

Values of $J(^{15}\text{N}, ^{15}\text{N})$ may vary in a complex fashion if there is a lone pair on each of the nuclei. The coupling constant is very sensitive to the dihedral angle ϕ between the lone-pair orbitals, since they interact to give bonding and antibonding (HOMO) combinations. Calculations on hydrazine, N_2H_4 , in which ϕ is near 90° show that $^1J(^{15}\text{N}, ^{15}\text{N})$ is negative and quite large for an N_2H_4 molecule with $\phi \approx 0^\circ$, falling to zero for the geometry with $\phi = 115^\circ$ and increasing to a large positive value for $\phi \approx 180^\circ$.²⁰⁷ Similarly, for planar systems such as diazenes as in azo compounds ($\text{RN}=\text{NR}$) or diazenido complexes ($\text{M}-\text{N}=\text{NR}$), $^1J(\text{N}, \text{N})$ values are large and negative for *cis* compounds with $\phi \sim 0^\circ$, but large and positive for *trans* compounds, with $\phi \approx 180^\circ$. In longer range couplings, ‘through-space’ orbital overlap provides an additional route for the transmission of coupling information.

The contributions to the spin–spin coupling that are mediated by p,d,... electrons are normally smaller than the contact contribution J^{fc} , and are very small for hydrogen, but may be sizeable if π bonding is present. The orbital term $J^{\text{o}}(\text{A}, \text{B})$ arising from the magnetic effect on nucleus B

of the orbital motion of an electron on nucleus A, and the spin–dipolar term $J^{\text{sd}}(\text{A}, \text{B})$ arising from direct interaction of the spin of an electron on nucleus A with the spin (magnetic dipole) of nucleus B, increase in magnitude with the bond order. In the dinitrogen molecule $\text{N}\equiv\text{N}$ with $^1J(^{15}\text{N}, ^{15}\text{N}) = 2.5 \text{ Hz}$,⁴⁵ a theoretical study²⁰⁸ found that the contact term made the smallest contribution, 0.82 Hz, compared with a dipolar contribution of -1.57 Hz and an orbital contribution of 3.35 Hz. Orbital and spin–dipolar contributions are large in the triply bonded molecules HCN, nitriles, and isonitriles.

The noncontact contributions, also, increase in magnitude when there are electronegative substituents on the coupled nuclei, because of a dependence on the radial term $\langle r^{-3} \rangle_{2p}$. Contact and noncontact contributions are all large in the benzonitrile *N*-oxide 2,4,6- $\text{C}_6\text{Me}_3\text{H}_2\text{CNO}$, giving an unusual overall value $^1J(^{15}\text{N}, ^{13}\text{C}) = (-)77 \text{ Hz}$.²⁰⁴

6.2 Couplings to Other Nuclei

Nitrogen couplings to other nuclei are normally dominated by the contact interaction. They are sensitive to s character in the relevant bonding orbitals and to the presence of lone-pair electrons. Discussion of the signs is most usefully in terms of the reduced coupling constant K since $\gamma(^{15}\text{N})$ is negative: thus, nitrogen couplings to fluorine are commonly measured in ^{14}N resonance as they are relatively large and the fluoro systems usually have low viscosity.

The periodic trends can be rationalized in terms of stabilization of bonding σ MOs and destabilization of nonbonding (lone pair) MOs with an increase in atomic number down the group or across the row of the Periodic Table. Amine–borane or aminoborane couplings 1K are positive (and relatively small). Values of $^1K(\text{C},\text{N})$ and $^1K(\text{Si},\text{N})$ are normally positive, but $^1K(\text{Sn},\text{N})$ values may be of either sign and $^1K(\text{Pb},\text{N})$ values are negative. Couplings to transition metals are normally positive.

Couplings of the type $^1K(\text{P},\text{N})$ involving P(III) are negative as for $^1K(\text{N},\text{N})$, while couplings to P(V) may be of either sign. Couplings of the type $^2K(\text{P},\text{N})$ are usually small, but may be quite large for *trans* interactions in metal complexes.

Values of $^1K(^{19}\text{F},\text{N})$ are expected to be negative because of the lone-pair contribution. The largest value is $^1J(^{19}\text{F},^{14}\text{N}) = 339 \text{ Hz}$ in $\text{FN}\equiv\text{NF}^+$, corresponding to the maximal $^1J(^{15}\text{N},\text{H}) = 135 \text{ Hz}$ in the nitrilium ion $\text{HC}\equiv\text{CNH}^+$. The value of $^1J(^{19}\text{F},^{14}\text{N})$ is 231 Hz in NF_4^+ compared with 158 Hz in NF_3 , another lone-pair effect.²⁸

Ligating nitrogen is relatively low in the empirical series of *trans* influence, though above halides or alkoxy ligands. The *trans* influence measures the tendency of a ligand by forming a strong bond to the metal to weaken the *trans* bond in a metal complex, so reducing the magnitude of coupling constants involving the *trans* bond.

6.3 Couplings as Criteria of Structure

Nitrogen couplings may be diagnostic of *cis-trans* or *syn-anti* stereochemistry, conformation, hydrogen bonding, and related medium effects. The couplings are enhanced by protonation, alkylation, or coordination of the nitrogen, and so may be diagnostic of chelation or proton migration. The largest magnitudes of couplings are observed in linear systems. In ligands which may be bent or linear in their attachment to a metal, such as nitroso ($-\text{N}=\text{O}$), diazenido ($-\text{N}=\text{N}-\text{R}$), or hydrazido(2-) ($=\text{N}-\text{NR}_2$) ligands, $\text{M}-\text{N}_\alpha$ coupling constants are reduced on bending; the protonation of the bent α -nitrogen in $[\text{PtCl}(\text{N}=\text{NPh})(\text{PEt}_3)_2]$ increases the $^1J(^{195}\text{Pt},^{15}\text{N})$ value from 157 to 510 Hz .¹²⁵ Couplings are also enhanced by flattening of a pyramidal group, delocalizing the s-type lone-pair electron density. Thus $^1J(\text{N},\text{H})$ values in the hydrazido(2-) ligand $-\text{N}-\text{NH}_2$ resemble those in amides rather than hydrazines, since the hydrazido(2-) ligand is flat.

Such relationships allow coupling constants to be estimated as required to optimize the experimental parameters. Equations relating 1J values to percentage s character in the bond^{197–199} can be used in this way if exceptional bond types are avoided.

7 SOLID STATE STUDIES^{6,7,13,14}

The fast growth of nitrogen NMR studies in the solid state is documented in the annual reports of work on solid state techniques, macromolecules, natural and synthetic, and shielding tensors (Section 5).⁷ Solid state NMR spectroscopy is increasingly being used in materials technology and for biological materials. Because of the volume of this work, reference can only be selective and directed towards new techniques or reviews.^{209,210}

Molecular biology has seen a great increase in nitrogen NMR.^{168,211,212} Peptide and protein backbones, planes, and side-chains can be studied with improved methods of orienting samples mechanically or magnetically. Ordered systems such as nucleoproteins or membrane–protein complexes²¹³ which are insufficiently soluble or mobile for solution studies, or insufficiently ordered for X-ray diffraction techniques, are becoming accessible to NMR study. Solid state NMR can provide spatial information which is lost by tumbling motions in solution, and can also monitor motions which are frozen or blurred in X-ray crystallographic studies.

For many systems, a combination of physical methods is needed; NMR to probe short-range interactions and X-ray crystallography methods showing long-range order.²¹⁴ Solid state NMR provides a useful link between X-ray crystallographic analysis and NMR solution studies, particularly as conformations may vary from solid to more fluid phases. Nitrogen spectra of biological material may be easier to interpret than carbon or proton spectra because of the relatively small number of nitrogens, characteristic shifts, and sizeable shielding range.

Nitrogen-14 properties measured in the solid state include electric field gradient (efg) tensors, quadrupole couplings, dipolar couplings, and spin diffusion²¹⁵ in studies of molecular structure and reorientation. Orientations of the ^{14}N efg tensors and carbonyl ^{13}C shielding tensors provide structural information in amino acids and peptides.²¹⁶ $\text{N}-\text{H}$ bond lengths have been determined with high accuracy from dipolar interactions of ^{14}N or ^{15}N with ^1H .²¹⁷ Static ^{14}N powder spectra were used to study electric field gradients and reorientation in NH_4NCS .²¹⁸ Information on ^{14}N dipolar and quadrupolar couplings is also obtained by lineshape analysis of resonances of a bonded neighbor, whether ^{13}C ,²¹⁹ ^{29}Si in nitrogen-containing ceramics,²²⁰ ^{195}Pt in $\text{K}_2[\text{Pt}(\text{CN})_4 \cdot 3\text{H}_2\text{O}]$,²²¹ etc.

Advantage can be taken of the high natural abundance of ^{14}N by using the ^{14}N nuclear quadrupole interaction to spread nitrogen spectra over a large range, more than compensating for quadrupolar line broadening. This method was used in ^{14}N and ^{13}C measurements of the CCN geometry and ^{14}N quadrupole coupling tensor in glycine single crystals.⁵⁷ The quadrupole interaction shifts the middle of the three ^{14}N energy levels ($I = 1$) relative to the other two, and produces a doublet splitting which is determined by the angular dependence of the first order quadrupole interaction. The second order quadrupole interaction, arising from the closeness of the Larmor and the quadrupole coupling frequencies, shifts the doublet somewhat and makes the overtone transition partially allowed. Information is thus available from the combination of the ^{14}N quadrupole splittings, second order ^{14}N quadrupole shifts, ^{14}N overtone frequencies, $^{14}\text{N}-^1\text{H}$ and $^{14}\text{N}-^{13}\text{C}$ dipolar splittings, and ^{13}C shielding tensor for determining orientations in a peptide plane in oriented samples. Cross polarization is very effective for ^{14}N spectra in amino acids, peptides, and proteins, because of strong NH coupling in the amido/peptide group. Peptide backbone conformations have been studied in this way by two-dimensional $^1\text{H}/^{14}\text{N}$ spectra and crystalline amino acids by $^{13}\text{C}/^{14}\text{N}$ spectra, with use also of $^1\text{H}/^{13}\text{C}/^{14}\text{N}$ triple resonance.^{58,222}

Most nitrogen work in the solid state is done in ^{15}N resonance, using the techniques developed for ^{13}C of static powder patterns or CP MAS methods with high-power

proton dipolar decoupling. The principal components of the shielding tensors (Section 5) are obtained from powder pattern lineshapes, or from the intensities of spinning side-bands at slower spinning rates. The orientation of the principal axis system in the molecular frame is found by the use of oriented specimens or by the observation of dipolar interactions.^{145,147}

Some solid state work has been done in natural abundance of ^{15}N , for example polymer studies of the α -helix and β -sheet components of homopolypeptides²²³ and Nylons,²²⁴ and of polyimines and the conducting polymers which they yield on oxidation.²²⁵ Adsorption studies may be possible in natural abundance of ^{15}N , the occlusion of NPr_4^+ cations in zeolites²²⁶ for example. Enrichment is usually necessary, however, and bioenrichment is particularly useful.

In a historic determination in 1972, the principal elements were reported for the nitrogen shielding tensor in the nitrate ion in ammonium nitrate, distorted by hydrogen bonding.²²⁷ Recently, the principal values of the nitrate shielding tensors in five solid phases of NH_4NO_3 , the phase transitions, crystal packing deformations, motional averaging at higher temperatures, and magnetic nonequivalence at low temperatures, have been examined by MAS and static NMR.²²⁸ Section 5 discusses shielding tensors reported for nitrogen in ammonia and amines, linear groups (iminophosphonium $\text{RN}\equiv\text{P}^+$, nitrile, isonitrile, N_2O , thiocyanate, N_2 , the dinitrogen ligand, $\text{P}\equiv\text{N}$, linear NO), planar groups (amide, peptide, heterocycle, aldimine, ketimine, oxime, nitroso dimer, nitrobenzene, nitrates, nitrite ion, nitroso compounds, azo or diazene, nitrogen oxides), and metal nitrosyls, linear and bent.

The nitrogen tensor has been used as a criterion of bending of the nitrosyl ligand (Section 5),¹⁸³ and to investigate nitrosyl swinging in solid $[\text{Co}(\text{NO})(\text{TPP})]$,¹⁸⁴ and the bent-linear fluxionality of the five-coordinate complex $[\text{RuCl}(\text{NO})_2(\text{PPh}_3)_2]\text{BF}_4$ in solution.²⁴

Catalytic processes are usefully investigated by ^{15}N CP MAS NMR. Acid sites of the Brønsted or of Lewis type may be distinguished by nitrogen compounds of differing basicity, as in studies of γ -alumina and mordenites by the sorption of pyridine or ammonia,^{229,230} and of zeolites by the sorption of ammonia²³¹ or trimethylamine,²³² cf. the interaction of pyridine with coals.²³³ Some adsorption work can be done by conventional NMR techniques, as in the study of acetonitrile on zeolites.²³⁴

Double cross polarization in doubly labeled ^{13}C – ^{15}N bonds, usually from ^1H to ^{13}C to ^{15}N , was developed to follow the progress of these bonds in vivo, in peptide and other linkages, an early application being to protein turnover in soybean leaves.²³⁵

The transferred echo double resonance (TEDOR) technique has been used to select a ^{13}C label by its dipolar coupling to ^{15}N , giving internuclear distances and geometries, in conjunction with the rotational echo double resonance (REDOR) technique measuring a dipolar coupling of the ^{13}C .²³⁶

Biological NMR studies using solid state techniques are discussed further in Section 9.

8 DYNAMICS^{2–7,237,238}

Dynamic processes with a range of timescales have been monitored by nitrogen NMR. Fast motions such as the switching of the ammonium ion in the $^{14}\text{NH}_4\text{Cl}$ lattice are

monitored by relaxation times (Section 3.1). Measurements of T_1 and NOE of the dipolar relaxation of ^{15}N by neighboring protons have been used to probe a variety of molecular motions, from segmental motions of large molecules to migrations of protons between nitrogens (Section 2). HH migrations between the nearby nitrogens, as in porphyrin or phthalocyanine molecules, were mentioned in Section 2.1, and a range of comparable systems has now been studied,²³⁹ most recently, double, triple, and quadruple proton transfers in pyrazoles.²⁴⁰

Hindered motions about N–X bonds are studied by lineshape analysis, 2D spectroscopy, multicoalescence experiments, saturation transfer, or equilibration methods, or by methods involving longitudinal or transverse relaxation times. A large number of isomerization processes involving N–X bonds have been reviewed as to methods of investigation, dynamics, thermodynamics, and theoretical interpretation in terms of quantum mechanical treatments or empirical correlations.²⁴¹

Examples of dynamic studies are fewer in inorganic chemistry. $^{14,15}\text{N}$ NMR spectroscopy has demonstrated kicking motions, as in the bent-linear fluxionality of the imido ligand $\text{M}=\text{NH}$ in concert with a second imido or an alkoxy ligand in solution.¹³⁹ A corresponding fluxionality of nitrosyls in solution was observed for the five-coordinate complex $[\text{RuCl}(\text{NO})_2(\text{PPh}_3)_2]^+$,²⁴ the averaged shift, the temperature dependence, and the equilibrium isotope effect with semienrichment suggesting that the trigonal bipyramidal form with two linear nitrosyls is present in dynamic equilibrium with the square-pyramidal form with one bent and one linear nitrosyl.²⁴ Swinging and spinning of the bent apical nitrosyl in solid $[\text{Co}(\text{NO})(\text{TPP})]$ was detected through changes in the nitrogen shielding tensor¹⁸⁴ (Section 5.5).

CIDNP enhancing absorption or emission in the NMR experiment, has been used in ^{15}N resonance to study a number of reactions in which radical pairs may be involved. The method is highly sensitive and species that give large signals may not be major intermediates. The contribution of radical pair mechanisms to the nitration of arenes by nitric and sulfuric acid mixtures is now thought to be small.²⁴² ^{15}N CIDNP has also been applied to the study of migrations of nitro groups,²⁴³ azo coupling,²⁴⁴ and the loss of dinitrogen from arene-diazonium salts.²⁴⁵ Stable nitroxide radicals, also, are accessible to NMR spectroscopic study.²⁴⁶

9 BIOMOLECULES^{2–7,9,13}

Biological applications of nitrogen NMR have increased in step with the development of NMR technology and have stimulated this development. Many examples of ^{14}N and ^{15}N NMR properties in biological materials have been given above together with the kinds of information now obtainable. Multidimensional correlation spectroscopy increasingly uses nitrogen as well as ^{13}C and ^1H .^{6,7} Other articles describing the use of nitrogen NMR in biomolecular and biological systems are listed at the end of this section.

Unique information can be obtained from nitrogen NMR on in vivo metabolism and cellular dynamics, as well as on protein (polypeptide) backbones, functional groups in enzymes, and DNA and RNA bases. Nitrogen-14 resonance may be used for material in which there is sufficient mobility for motional

averaging^{247,248} and with solid state techniques making use of the quadrupolar interaction (Section 7). Bioenrichment of ^{15}N allows this to be used as a biological tracer in the absence of a stable radioisotope of nitrogen (^{13}N , the most stable, has a halflife of only 10 min). Highly selective bioenrichment can be obtained by supplying the organism with a ^{15}N -labeled nutrient, such as an amino acid. For ^{15}N work in the liquid phase, the dependence of the relaxation time $T_{1\rho}$ and the NOE on the molecular size has been discussed (Section 2.1).

Techniques and applications to biological systems have been described in a number of reviews²⁴⁹ dealing with nucleic acids and nucleotides, enzyme systems, and intact cells,²⁵⁰ amino sugars,²⁵¹ intermolecular interactions,²⁵² solid state peptide studies,¹⁶⁸ and work of pharmacological interest.^{253,254} Nitrogen-15 spectra can resolve differences between diastereotopomers, as of 8-benzyl-5,6,7,8-tetrahydroquinoline in solutions of optically active carboxylic acids.²⁵⁵

In living cells, molecules that are sufficiently mobile can be studied by solution state techniques and bioenrichment of ^{15}N has been used to advantage. The first in vivo study was of a fungus *Ustilago sphaerogena* grow with ^{15}N -ammonium acetate as a nitrogen source, the resonances of small peptides being observed.²⁵⁶ The mobilities of components of bacterial cell walls were estimated quite early on from ^{15}N NOE values, the observable resonances being those of mobile cross-linking groups.²⁵⁷ The biosynthesis of amino acids from ^{15}N -ammonium salts and their intracellular environment was followed in the fungus *Neurospora crassa*²⁵⁸ and in *Brevibacterium lactofermentum*.²⁵⁹

Nitrogen NMR is being used increasingly in metabolic studies using solid state techniques. In DNA from *E. coli* grown with $^{15}\text{NH}_4\text{Cl}$ as the source of nitrogen, 13 of the 14 nitrogens in the bases were distinguished by their dipolar coupling to protons.²⁶⁰ This allowed the NH bond lengths to be measured, complementing the information available from X-ray and neutron diffraction.²⁶¹ DNA and protein spectra were obtained from the filamentous bacteriophage fd infecting the *E. coli*, and 2D spectra from oriented molecules of the virus.²⁶²

Solid state techniques have been developed for the study of nitrogen metabolism in growing plants using double cross polarization (DCP MAS) NMR (Section 8). This required double enrichment in vivo with $^{15}\text{NH}_4^{15}\text{NO}_3$ and pulsed $^{13}\text{CO}_2$ labeling, to form ^{13}C - ^{15}N bonds, examined in intact or lyophilized material. Such DCP MAS NMR has been used to follow the metabolism of methionine²⁶³ in soybean cotyledons, and also of allantoin²⁶⁴ and alanine²⁶⁵ in *Aerococcus viridans*.

Double labeling can establish biosynthetic pathways, such as cyclization to form the N-C(5) bond in isopenicillin N observed as a $^1J(^{15}\text{N},^{13}\text{C})$ coupling.²⁶⁶

With a variety of techniques, therefore, in vivo observation of components of appropriate mobility is now replacing the use of lyophilized (freeze-dried) tissue. Indeed, ^{15}N -labeled glycine has been detected by a probe implanted between the liver lobes, fixed to the abdominal wall, of a live rat.²⁶⁷

1 INTRODUCTION

With the exception of argon, all of the noble gases have at least one naturally abundant nuclide which is amenable to NMR investigation, i.e., ^3He , ^{21}Ne , ^{83}Kr , ^{129}Xe , and ^{131}Xe . Xenon is the most favorable noble gas from an NMR standpoint as it possesses a spin- $\frac{1}{2}$ nuclide having a high natural abundance, viz. ^{129}Xe ($N = 26.44\%$). There is also a quadrupolar xenon nuclide, ^{131}Xe ($I = \frac{3}{2}$, $N = 21.18\%$), but this has not been used for studies of chemical structure. Helium also has a very low abundance spin- $\frac{1}{2}$ nuclide, ^3He ($N = 1.3 \times 10^{-4}\%$), and is of interest to physicists in their studies of solid and superfluid states of helium. Helium-3 NMR spectroscopy has recently found chemical applications in the study of the endohedral fullerenes, He@C_{60} and He@C_{70} .^{1,2} Argon has no stable nuclide of nonzero spin, a rare occurrence in the Periodic Table. Both neon and krypton possess quadrupolar nuclei (^{21}Ne , $I = \frac{3}{2}$, $N = 0.26\%$ and ^{83}Kr , $I = \frac{9}{2}$, $N = 11.55\%$), but NMR work has largely been confined to physics. The only noble gases known to form isolable compounds are krypton, xenon, and the metalloid noble gas radon. No information is available concerning the nuclear spins of naturally produced radon isotopes. Moreover, the inherent radiation hazard that accompanies the intense radioactivity of radon and the required tracer level experimentation would likely preclude any attempt at NMR characterization of radon compounds even if a suitable spin-active nuclide was available. Only ^{129}Xe NMR spectra have been observed in chemical environments other than the pure element. Although Kr compounds have been characterized by ^{19}F NMR spectroscopy, none of the known Kr compounds have been studied by ^{83}Kr NMR spectroscopy.^{3–6}

Comprehensive reviews of this subject are available in ‘NMR and the Periodic Table’ in the chapter by Schrobilgen⁷ and in ‘Multinuclear NMR’ in the chapter by Jameson,⁸ up to the years 1978 and 1987, respectively. Developments in noble gas chemistry have been reviewed by many authors^{9–17} and include crystallographic and spectroscopic evidence, in which ^{129}Xe and ^{19}F NMR studies of xenon compounds and krypton compounds are included. Xenon fluorides, XeOF_4 , and their complexes are the only thermodynamically stable xenon compounds. The majority of xenon and krypton compounds are kinetically unstable at temperatures approaching ambient and all are potent oxidizers; in fact, KrF^+ salts are the most potent chemical oxidants known.^{3,18} Compound properties dictate that the majority of their NMR spectra be obtained

at temperatures well below ambient and that NMR samples be prepared in oxidatively resistant and rigorously anhydrous solvents. The chemistry of krypton is far less extensive than that of xenon. Consequently, a high proportion of the second part of this article concerns ^{129}Xe NMR spectroscopy. The favorable ^{129}Xe relaxation times (T_1) in various species in solution (285–780 ms)^{19,20} which allow reasonable pulse repetition rates and the high receptivity of the nuclide (31.8 relative to that of ^{13}C) make ^{129}Xe NMR spectra relatively easy to acquire using modern Fourier transform spectrometers. The third part of this article briefly surveys NMR studies of intermolecular interactions with ^3He , ^{21}Ne , ^{83}Kr , ^{129}Xe , and ^{131}Xe .

2 NMR STUDIES OF STRUCTURE AND BONDING IN NOBLE GAS COMPOUNDS

Since the discovery of noble gas reactivity,²¹ xenon compounds, including halides, oxides, oxofluorides, oxo salts, and numerous covalent derivatives with a number of compounds covalently bonded to other polyatomic ligands have been prepared.^{9–17} Additionally, the fluorides and oxofluorides of xenon form a variety of fluoro and oxofluoro cations and anions in their reactions with strong Lewis acid acceptors and fluoride ion donors, respectively.¹⁴ Examples of xenon covalently bonded to fluorine, oxygen, nitrogen, carbon, and to xenon itself are now known. An early report of a xenon–boron bond has never been substantiated.²² Xenon has by far the most extensive chemistry of the noble gas elements and the ^{129}Xe nuclide is ideal for the thorough investigation of a heavy nucleus since it can be obtained in a variety of compounds in a wide range of oxidation states and geometries (Tables 1 and 2). Covalent compounds containing Xe–F, Xe–O, Xe=O, Xe–N, Xe–C, and fluorine bridge bonds, denoted $\text{Xe} \cdots \text{F}$, have been characterized spectroscopically and by X-ray crystallography. The known xenon oxidation states and geometries categorized according to the terminology of the VSEPR model of molecular geometry⁵⁶ are represented by the following examples: +2 in xenon species having AX_2E_3 [XeF_2 , $\text{Xe}(\text{OTeF}_5)_2$, $\text{FXeN} \equiv \text{CH}^+$] and AXE_3 [XeF^+ , $\text{XeN}(\text{SO}_2\text{F})_2^+$] types; +4 in AX_5E_2 (XeF_5^-), AX_4E_2 [XeF_4 , $\text{Xe}(\text{OTeF}_5)_4$], and AX_3E_2 (XeF_3^+ , XeOF_2) types; +6 in AX_8E (XeF_8^{2-}), AX_7E (XeF_7^-), AX_6E (XeF_6 , XeOF_5^-), AX_5E [XeF_5^+ , XeOF_4 , $\text{OXe}(\text{OTeF}_5)_4$], AX_4E (XeOF_3^+ , XeO_2F_2), and AX_3E (XeO_3 , XeO_2F^+) types; and +8 in AX_6 (XeO_6^{4-} , XeO_2F_4), AX_5 (XeO_3F_2), and AX_4 (XeO_4) types, where A denotes the central xenon atom, X a bond domain, and E an electron lone pair domain. In addition, the $+\frac{1}{2}$ oxidation state is represented by the emerald green paramagnetic cation Xe_2^+ , which has been stabilized in solution.⁵⁷ The majority of xenon species synthesized to date have been characterized by ^{129}Xe NMR spectroscopy. Because ^{129}Xe NMR spectroscopy is not limited by the need to isolate a species in the solid state, low-temperature ^{129}Xe NMR spectroscopy has proven invaluable for the characterization of unstable xenon species in the reactive solvent media in which they are frequently generated. The chemistry of krypton is far less extensive than that of xenon. Krypton compounds are limited to only a single oxidation state, namely +2, and to AX_2E_3 [KrF_2 , $\text{Kr}(\text{OTeF}_5)_2$, $\text{FKrN} \equiv \text{CH}^+$] and AXE_3 (KrF^+) geometrical

types. Like xenon(II) compounds, krypton(II) compounds have been characterized by ^{19}F NMR spectroscopy, but no ^{83}Kr – ^{19}F couplings have been observed.^{3–6}

2.1 ^{129}Xe Chemical Shifts

Theoretical approximations have been developed which make it easier to interpret the chemical shifts of ^{129}Xe and other heavy nuclei in chemical terms. One such approximation represents the shielding of a nucleus like ^{129}Xe by the local terms $\sigma^{\text{d}}_{\text{Xe}}$ and $\sigma^{\text{p}}_{\text{Xe}}$, which are calculated by Ramsey's theory⁵⁸ applied to the electrons on Xe only.⁵⁹ Because ^{129}Xe exhibits a large dynamic range of ^{129}Xe chemical shifts (–5460 to +2077 ppm, Table 1), $\sigma^{\text{d}}_{\text{Xe}}$ is assumed to differ little from the free-atom value so that chemical shift trends are largely ascribable to variations in the dominant $\sigma^{\text{p}}_{\text{Xe}}$ term. Jameson and Gutowsky⁶⁰ used this approach in an early theoretical study to show that ^{129}Xe chemical shifts can be calculated with considerable accuracy in the limited number of cases then known by application of equation (1). These calculations show that a localized description of the bonding employing d hybridization provides a more satisfactory description than a delocalized description without d hybridization. Moreover, the approach shows that ΔE , $\langle r^{-3} \rangle_{5p}$ and $\langle r^{-3} \rangle_{5d}$ can be regarded as essentially constant over the entire range of $\delta(^{129}\text{Xe})$ so that P_i and D_i determine variations in $\delta(^{129}\text{Xe})$.

$$\sigma^{\text{p}} \simeq (-\mu_0/4\pi)(4\mu_{\text{B}}^2/\Delta E)[\langle r^{-3} \rangle_{np}P_i + \langle r^{-3} \rangle_{nd}D_i] \quad (1)$$

The large dynamic chemical shift range exhibited for ^{129}Xe is anticipated from trends among other nuclei. Existing experimental data show that chemical shift ranges tend to increase with atomic number Z across a given row of the Periodic Table and down a given group, and may be correlated with the variation of the radial term $\langle r^{-3} \rangle_{np}$ for the valence p electrons of the free atom.⁶¹ Since the paramagnetic shielding term $\sigma^{\text{p}}_{\text{Xe}}$ has this radial dependence, this places xenon ($Z = 54$) in a category among nuclei having one of the larger dynamic chemical shift ranges. Relativistic effects, which vary with Z^2 , also make a significant contribution to the chemical shift range for ^{129}Xe as exemplified by the diamagnetic shielding term $\sigma^{\text{d}}_{\text{Xe}}$ of atomic xenon, which has a relativistic value of 7040 ppm⁶² compared with a nonrelativistic value of 5642 ppm.⁶³

While absolute shielding components have not been measured for xenon in its various oxidation states, theoretical arguments predict rather large anisotropies: $(\sigma_{\parallel} - \sigma_{\perp}) = +5125$ to $+7185$ ppm for XeF_2 ; $+725$ to $+3940$ ppm for XeF_4 , and $+365$ to $+1500$ ppm for XeOF_4 .⁶⁰ Xenon quadrupole coupling constants, $|e^2qQ|$, obtained from Mössbauer experiments, yield values of the electric field gradient at the xenon nucleus, which, in turn, are a measure of the anisotropy of the $\sigma^{\text{p}}_{\text{Xe}}$ term.⁸

There have been no recent calculations of Xe nuclear shielding or spin–spin coupling constants, so that the approach to the discussion of ^{129}Xe chemical shifts must remain an essentially empirical one. Of particular interest is the great sensitivity of the ^{129}Xe chemical shift to (1) the formal oxidation state, (2) the ionic character of the Xe–L bond, where L is F, O, or a polyatomic ligand which is bonded to Xe through O, N, or C, (3) the formal charge on the xenon

atom, (4) isotropic effects, and (5) medium and temperature effects.

It is apparent from Table 1 that the paramagnetic shielding contribution to $\delta(^{129}\text{Xe})$ mainly depends upon the formal oxidation number of xenon and is essentially in the order $\sigma(^{129}\text{Xe})$: $\text{Xe(0)} > \text{Xe(II)} > \text{Xe(IV)} > \text{Xe(VI)} > \text{Xe(VIII)}$, i.e., $\delta(^{129}\text{Xe}) = -5460$ to -5331 ppm for Xe(0) , -3769.3 to -574 ppm for Xe(II) , -662.8 to $+595$ ppm for Xe(IV) , -211.8 to $+704.3$ ppm for Xe(VI) , and $+2077$ ppm for Xe(VIII) , with considerable overlap in chemical shift ranges for Xe(IV) and Xe(VI) . The lower shieldings for xenon in XeF_4 [$\delta(^{129}\text{Xe}) = 166.1$ – 316.9 ppm] and XeF_3^+ [$\delta(^{129}\text{Xe}) = 595$ ppm] relative to the Xe(VI) species are in marked contrast to the corresponding $\sigma(^{19}\text{F})$ chemical trends, which vary monotonically with oxidation state, i.e., $\text{Xe(VI)} < \text{Xe(IV)} < \text{Xe(II)}$.⁶⁴ The observed $\sigma(^{129}\text{Xe})$ trend is, however, in agreement with the trend calculated by Jameson and Gutowsky⁶⁰ for $\text{XeF}_4 < \text{XeOF}_4 < \text{XeF}_6 < \text{XeF}_2$. Within a given oxidation state several trends are also apparent.

A monotonic deshielding of the central xenon atom for the two series $(\text{XeF}_6)_4$, XeOF_4 , XeO_2F_2 , XeO_3 , and XeF_5^+ , XeOF_3^+ , XeO_2F^+ (additive for the latter series) is observed with increasing oxygen substitution (Table 1), and may be attributed to contributions of the sort $\text{Xe}=\text{O} \leftrightarrow \text{Xe}^+-\text{O}^-$, which serve to increase P_i and D_i , decreasing the $\sigma^{\text{p}}_{\text{Xe}}$ term. The opposite effect is observed upon increasing oxygen substitution in the homologous series of mixed F/OTeF₅ derivatives of Xe(II) , Xe(IV) , and Xe(VI) . Within each of the neutral series $\text{XeF}_{2-n}(\text{OTeF}_5)_n$, $\text{XeF}_{4-n}(\text{OTeF}_5)_n$, $\text{O}=\text{XeF}_{4-n}(\text{OTeF}_5)_n$, and $\text{O}_2\text{XeF}_{2-n}(\text{OTeF}_5)_n$ and the cation series $\text{XeF}^+/\text{XeOTeF}_5^+$, $\text{O}_2\text{XeF}^+/\text{O}_2\text{XeOTeF}_5^+$, $\text{XeF}_{3-n}(\text{OTeF}_5)_n^+$, and $\text{O}=\text{XeF}_{3-n}(\text{OTeF}_5)_n^+$, the ^{129}Xe chemical shifts are found to be additive (Table 1), exhibiting increased shielding with increasing number of OTeF₅ groups. These trends reflect the lower effective electronegativity of the OTeF₅ group compared with that of fluorine. This behavior is typified by the equations:

$$\delta(^{129}\text{XeOL}_4) = -43.9n - 26.1 \quad (2)$$

and

$$\delta(^{129}\text{XeOL}_3^+) = -91.1n + 232.7 \quad (3)$$

where n = number of OTeF₅ groups.^{46,49}

For all oxidation states, the Xe nucleus of the cation having one less F or OTeF₅ group is less shielded: $\sigma(^{129}\text{Xe})$: $\text{XeL}_n > \text{XeL}_{n-1}^+$ and $(\text{O}=\text{O})_m\text{XeL}_n > (\text{O}=\text{O})_m\text{XeF}_{n-1}^+$. This is illustrated by the chemical shifts of XeF_n and XeF_{n-1}^+ where $n = 2$: $\delta(^{129}\text{Xe}) = -2009$ to -1592 ppm, -991 to -574 ppm; $n = 4$: $\delta(^{129}\text{Xe}) = +166.1$ to $+316.9$, $+595$ ppm; $n = 6$: $\delta(^{129}\text{Xe}) = -35$ to -60.8 , -23.9 to $+131.8$ ppm, and by the chemical shifts of $(\text{O}=\text{O})_m\text{Xe}(\text{OTeF}_5)_n$ and $(\text{O}=\text{O})_m\text{Xe}(\text{OTeF}_5)_{n-1}^+$, where $n = 2$, $m = 0$: $\delta(^{129}\text{Xe}) = -2447.4$ to -2327 ppm, -1608 to -1472 ppm, $n = 4$, $m = 0$: $\delta(^{129}\text{Xe}) = -662.8$ to -637 ppm, -341.9 ppm, $n = 4$, $m = 1$: $\delta(^{129}\text{Xe}) = -211.8$ to -170.3 ppm, -1.9 ppm, $n = 2$, $m = 2$; and $\delta(^{129}\text{Xe}) = 131$ ppm, 543.0 ppm.

Xenon-129 NMR spectra have been recorded for only three xenon anions, XeF_5^- , XeF_7^- , and XeOF_5^- . The ^{129}Xe nucleus of the anion is, as anticipated, significantly more shielded than that of the neutral fluoride, i.e. XeF_4 and XeF_5^- : $\delta(^{129}\text{Xe}) = 166.1$ to 316.9 ppm, -527.0 ppm; XeF_6 and XeF_7^- : $\delta(^{129}\text{Xe}) = -35$ to -60.8 ppm, -169.3 ppm; and XeOF_4 and XeOF_5^- :

$\delta(^{129}\text{Xe}) = 0 \text{ ppm}$, -357.9 ppm (spectra of anions obtained in CH_3CN solvent).

The majority of known xenon compounds contain xenon in the +2 oxidation state and have been extensively studied by ^{129}Xe NMR spectroscopy. The xenon shielding in Xe(II) species follows the trend $\sigma(^{129}\text{Xe})$: $\text{XeL}_2 > \text{FXeL} > (\text{LXe})_2\text{F}^+ > \text{XeL}^+$, where $\text{L} = \text{F}$, OTeF_5 , OSO_2F , and $\text{N}(\text{SO}_2\text{F})_2$, and is found to hold without exception. NMR studies of xenon(II) derivatives containing XeF groups have established trends among ^{19}F and ^{129}Xe chemical shifts and $^1J(^{129}\text{Xe}, ^{19}\text{F})$ couplings (vide infra) that are of importance in assessing the relative covalent characters of Xe-L and terminal Xe-F bonds in compounds of the type F-Xe-L and F-Xe-L^+ , where L is a terminal fluorine, bridging fluorine or a ligand bonded to Xe(II) through oxygen or nitrogen.^{7,8,16,37} In general, as the ionic character of the Xe-L bond increases, the covalent character of the terminal Xe-F bond increases, increasing the formal charge on xenon and deshielding the xenon nucleus, and vice versa.¹⁶ This trend is also paralleled by increasing values of $^1J(^{129}\text{Xe}, ^{19}\text{F})$ and decreasing values of $\delta(^{19}\text{F})$ for the terminal XeF group (vide infra). The pattern observed in the ^{19}F and ^{129}Xe NMR spectra is corroborated by measurements of Xe-F stretching frequencies provided by Raman spectroscopy and, in a number of cases, by Xe-F bond lengths. Bonding models for XeF_2 indicate a high degree of Xe-F ionic character. The charge distribution represented as $\text{F}^{-\frac{1}{2}}\text{Xe}^+\text{F}^{-\frac{1}{2}}$ has been predicted by theoretical treatments⁶⁵ and is arrived at using either a three-center-two-electron bonding model or a valence bond description. A simple valence bond description also satisfactorily accounts for qualitative trends in xenon shieldings, $^1J(^{129}\text{Xe(II)}, ^{19}\text{F})$ couplings (vide infra), bond lengths, and vibrational frequencies in Xe(II) species.¹⁶ The bonding in XeL_2 , XeL^+ , and the adduct cations LXeF^+ ($\text{L} = \text{fluorine, nitrogen- or oxygen-bonded ligand, carbon-bonded ligand only in LXe}^+$ types) may be represented by valence bond structures I–VI, where structures I and IV are the least important contributing structures.

Accordingly, structures II and III apply to formally neutral species so that the XeF_2 molecule has a formal Xe-F bond order of $\frac{1}{2}$ whereas for LXeF the Xe-F bond order is $\geq \frac{1}{2}$ and < 1 , approaching 1 in the most weakly coordinated cases of XeF^+ and XeOTeF_5^+ in SbF_5 solvent. Due to the low fluoride ion basicities of the polymeric $\text{Sb}_n\text{F}_{5n+1}^-$ anions, which exist in solutions of XeF^+ and XeOTeF_5^+ in SbF_5 , these solutions provide the closest approximations to free XeF^+ and XeOTeF_5^+ cations in solution, providing Xe-F and Xe-O formal bond orders that approach unity and Xe shieldings that are dramatically decreased relative to those of the parent molecules, i.e., XeF^+ (574 ppm, SbF_5 solvent) and XeF_2 (-1592 to -2009 ppm); XeOTeF_5^+ (-1472 ppm, SbF_5 solvent), FXeOTeF_5 (-2051 to -2067 ppm), and $\text{Xe}(\text{OTeF}_5)_2$ (-2327 to -2447.4 ppm). The chemical shift of XeF^+ in SbF_5 represents the most deshielded ^{129}Xe resonance observed

for an Xe(II) species. As the base strength of L increases (group electronegativity decreases), the Xe-L bond becomes progressively more covalent, the shielding of the xenon nucleus increases as illustrated above by XeL_2 and XeL^+ , where $\text{L} = \text{F}$, and/or OTeF_5 . In cases where both fluorines are replaced by ligands that provide Xe-L bonds of greater covalent character than Xe-F bonds, the ^{129}Xe shieldings increase relative to that of XeF_2 and FXeL (Table 1). The opposite effect is observed for the ^{19}F shieldings of L-Xe-F (and L-Xe-F^+) species. Plots of the ^{129}Xe chemical shift versus the ^{19}F chemical shift of the terminal fluorine on xenon result in separate linear relationships, one for XeF groups bonded to oxygen and another for XeF groups bonded to bridging fluorines; the lines intersect, as expected, in the vicinity of the weakly fluorine-bridged XeF^+ cation in SbF_5 solvent.³⁷ The reader is cautioned that, where possible, such comparisons need to be made under the same solvent and temperature conditions (see Section 2.4 below).

Nitrogen bases such as nitriles, $\text{HC}\equiv\text{N}$, perfluoropyridines, and *s*-trifluorotriazine that are resistant to oxidation by the strongly oxidizing XeF^+ , XeOSeF_5^+ , and XeOTeF_5^+ cations form Lewis acid–base adducts with all three cations.^{16,23,43,44} The ^{129}Xe shieldings indicate a significant measure of XeL^+ character and have been used to assess the nature of the Xe-N donor–acceptor bond. With corroboration from the vibrational spectra of L-Xe-F^+ cations, the nature of the Xe-N donor–acceptor bond can be rationalized in terms of structures V and VI. For the L-Xe-F^+ cations, resonance structure VI is dominant relative to structure V as a result of the high charge localization. Thus, the Xe-N bonds of L-Xe-F^+ cations are best described as essentially ionic interactions of the ligand L and XeF^+ , and exhibit deshielded xenon nuclei that are consistent with weakly coordinated XeF^+ cations (Table 1). In general, this class of Xe(II) species exhibits trends similar to those of the neutral L-Xe-F species as the electron donor properties of L are varied, i.e., greater *s* contribution to the hybridization of the ligand donor atom lowers the effective electronegativity of the nitrogen donor atom, resulting in a more ionic Xe-L bond (greater contribution from structure V), producing greater XeF^+ character and a more shielded xenon nucleus.⁶⁶ This is illustrated in Table 1 by a series of cations containing formally *sp*-hybridized nitrogen (e.g., $\text{F}_3\text{S}\equiv\text{N-XeF}^+$, $\text{RC}\equiv\text{N-XeF}^+$) in which the xenon nuclei are consistently more deshielded (more ionic Xe-N bonds) than the xenon nuclei in cations containing formally *sp*²-hybridized nitrogen (e.g., $4\text{-CF}_3\text{C}_5\text{F}_4\text{N-XeF}^+$, $\text{C}_5\text{F}_5\text{N-XeF}^+$, *s*- $\text{C}_3\text{F}_3\text{N}_2\text{N-XeF}^+$).

In the extreme case of a formally neutral L-Xe-F species where L is strongly electron donating, structure II dominates to the extent that the Xe-F bond is completely ionized. Such XeL^+ cations are known in which xenon is bonded through strongly electron donating carbon and nitrogen ligand groups and are typified by $\text{C}_6\text{F}_5\text{Xe}^+$ (-3769.3 ppm), $\text{F}_5\text{TeN(H)Xe}^+$ (-2903 ppm), $\text{F}_5\text{SN(H)Xe}^+$ (-2886 ppm), and $\text{F}_4\text{S=NXe}^+$ (-2672 ppm) and are classified, on the basis of their ^{129}Xe shieldings, as the most highly covalent bonds formed by Xe(II) . With the exception of the free Xe atom, the strong electron donating properties of Xe(II) result in the most shielded xenon environments known.

2.2 Isotopic Effects in Krypton and Xenon Compounds

The secondary effects of krypton isotopes on the nuclear shielding of ^{19}F have been reported for three krypton compounds: $^1\Delta^{19}\text{F}(m'/m\text{Kr}) = -0.0102 \text{ ppm u}^{-1}$ for KrF_2 ,⁶⁶ $-0.0138 \text{ ppm u}^{-1}$ for $\text{FKrN}\equiv\text{CH}^+$,⁵ and $-0.0105 \text{ ppm u}^{-1}$ for $\text{FKrN}\equiv\text{CF}_3^+$.⁶ The ^{19}F resonances arising from $^{83}\text{KrF}_2$ and $^{131}\text{XeF}_2$ are not detectable owing to line broadening from the quadrupolar ^{131}Xe ($I = \frac{3}{2}$) and ^{83}Kr ($I = \frac{9}{2}$) nuclei.⁶⁷ The only secondary effects of xenon isotopes on the nuclear shielding of ^{19}F have been reported for XeF_2 : $^1\Delta^{19}\text{F}(m'/m\text{Xe}) = -0.00118 \text{ ppm u}^{-1}$.⁶⁷ The only secondary isotopic effects on the nuclear shielding of ^{129}Xe that are known arise from oxygen isotopes: $^1\Delta^{129}\text{Xe}(m'/m\text{O}) = -0.29 \text{ ppm u}^{-1}$ for XeOF_4 ,⁴⁹ -0.26 ppm u^{-1} for XeO_2F_2 ,⁴⁹ and $-0.345 \text{ ppm u}^{-1}$ for XeOF_3^+ .⁵⁴ All ^{19}F and ^{129}Xe chemical shifts of the various isotopomers of these molecules exhibit strict proportionality to the mass factor, $(m' - m)/m'$. No isotopic dependence of a spin–spin coupling to ^{129}Xe has been reported.

2.3 Spin–Spin Coupling to ^{129}Xe

One-bond ^{129}Xe – ^{19}F scalar couplings are summarized in Table 1 and those involving ^{129}Xe coupled to other nuclei are listed in Table 2. Other than an early study of $^1J(^{129}\text{Xe}, ^{19}\text{F})$ couplings, there have been no theoretical treatments of spin–spin coupling with xenon beyond the average energy approximation used in the theory of xenon and fluorine chemical shifts of XeF_2 , XeF_4 , XeF_6 , and XeOF_4 .⁶⁰ It is generally accepted that the Fermi contact mechanism is the dominant term in the spin–spin coupling constants involving xenon.⁶¹ Owing to the high atomic number of xenon, the spin–spin coupling constants, as well as xenon nuclear shieldings, experience significant relativistic effects. Because the s-electron density at the nucleus, $|\Psi_s(0)|^2$, appears in the Fermi contact term of the spin–spin coupling, this term should be evaluated relativistically. Such a relativistic correction is estimated to increase $|\Psi_s(0)|^2$ by a factor of 1.484.^{68,69}

The moduli of one-bond coupling constants, $^1J(^{129}\text{Xe}, ^{19}\text{F})$, associated with the different oxidation states of xenon can be used as a diagnostic tool to confirm the formal oxidation number of a xenon species by virtue of their nonoverlapping ranges, $^1J(^{129}\text{Xe}, ^{19}\text{F})$: $\text{Xe(VI)} < \text{Xe(IV)} < \text{Xe(II)}$, and correspond to the ranges $^{129}\text{Xe(II)}$ –terminal ^{19}F : 5583–7594 Hz, $^{129}\text{Xe(II)}$ –bridging ^{19}F : 4828–5117 Hz, $^{129}\text{Xe(IV)}$ – ^{19}F : 2384–3823 Hz, $^{129}\text{Xe(VI)}$ – ^{19}F : 95–1400 Hz. The variation with oxidation number is in agreement with trends generally noted for the dependence of one-bond scalar couplings on oxidation number.⁶¹

Empirical correlations between ^{19}F chemical shifts and one-bond ^{129}Xe – ^{19}F coupling constants exist in the literature. There is a smooth curve correlating the modulus of $^1J(^{129}\text{Xe}, ^{19}\text{F})$ with $\delta(^{19}\text{F})$ for all oxidation states of xenon.⁶⁴ The correlation provides a rationale for the small $^1J(^{129}\text{Xe}, ^{19}\text{F})$ couplings observed for XeO_2F^+ , $(\text{XeF}_6)_4$, and the equatorial fluorines of XeF_5^+ , if it is assumed that a change in the signs of the coupling constants occurs over the series in the vicinity of these species, and implies that the signs of the axial and equatorial couplings of XeOF_3^+ and the axial coupling of XeF_5^+ are likely to be opposite in sign with respect to the remaining species. No absolute sign

determinations have been made for any of the couplings to ^{129}Xe . However, the signs of the reduced couplings, $^1K(\text{Xe}, \text{F})$, may be inferred by considering the isoelectronic series of Sn(IV) – I(VII) hexafluoro species.^{64,70} A near-linear relationship is obtained when $K(\text{X–F})^{\frac{1}{2}}$ is plotted versus Z and no change of sign is assumed along the series.⁷¹ Since the signs of $^1K[\text{Sn(IV)}, \text{F}]$ and $^1K[\text{Te(VI)}, \text{F}]$ couplings have been determined to be negative, and the modulus of $^1K(\text{X}, \text{F})$ increases along the series $\text{SnF}_6^{2-} < \text{SbF}_6^- < \text{TeF}_6 < \text{IF}_6^+$, the hypothetical Xe(VIII) cation, XeF_6^{2+} , would possess the most negative value for the reduced one-bond coupling. The signs of $K(\text{Xe}, \text{F})$ for Xe(VIII) and Xe(VI) species excepting XeOF_4 , XeO_2F_2 , and possibly XeF_6 and XeO_2F^+ , are taken as positive. Confirmation of the aforementioned ^{19}F chemical shift and ^{129}Xe – ^{19}F coupling constant correlation and sign change awaits ^{19}F and ^{129}Xe NMR data on known Xe(VIII) compounds such as XeO_3F_2 and XeO_2F_4 .

The $^1J(^{129}\text{Xe}, ^{19}\text{F})$ coupling is sensitive to the charge on the xenon. In the case of Xe(II) , it varies with the degree of XeF^+ character in L–Xe–F and L–Xe–F^+ species with the largest values observed for essentially ‘free’ XeF^+ in SbF_5 (7210 Hz) and $(\text{FXe})_2\text{F}^+$ (6662–6740 Hz). Accordingly, $^1J[^{129}\text{Xe(II)}, ^{19}\text{F}]$ trends may be rationalized in terms of valence bond structures I–VI and described in terms similar to those used to rationalize trends in $^{129}\text{Xe(II)}$ chemical shifts (vide supra). Thus, smaller $^1J[^{129}\text{Xe(II)}, ^{19}\text{F}]$ values are observed for F–Xe–L and F–Xe–L^+ species having the more covalent Xe–L bonds as illustrated by $\text{FXeN}(\text{SO}_2\text{F})_2$ (5572–5624 Hz) and *cis*- and *trans*- FXeOIOF_4 (5803–5913 Hz). Consequently, smooth correlations are observed not only where $^1J[^{129}\text{Xe(II)}, ^{19}\text{F}]$ increases with increasing $\delta(^{129}\text{Xe})$, but $^1J[^{129}\text{Xe(II)}, ^{19}\text{F}]$ is also noted to increase with decreasing $\delta(^{19}\text{F})$, increasing the $\text{Xe(II)}\text{–F}$ stretching frequency and decreasing the $\text{Xe(II)}\text{–F}$ bond length.^{7,16}

Although the trend of increasing $^1J(^{129}\text{Xe}, ^{19}\text{F})$ with increasing covalent character (decreasing Xe–F bond length) is clear for Xe(II) , bond length data available for comparison with $^1J(^{129}\text{Xe}, ^{19}\text{F})$ values of higher oxidation state species are sparse. The trend of increasing $^1J(^{129}\text{Xe}, ^{19}\text{F})$ with decreasing bond length is apparent in the three cases for which two bond lengths and couplings can be compared in the same species, viz: XeF_3^+ [$^1J[^{129}\text{Xe(IV)}, ^{19}\text{F}_{\text{ax}}] = 2384 \text{ Hz}$; Xe–F_{ax} distance = 191 pm and $^1J[^{129}\text{Xe(IV)}, ^{19}\text{F}_{\text{eq}}] = 2609 \text{ Hz}$; Xe–F_{eq} distance = 184 pm], XeF_5^+ [$^1J[^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{ax}}] = 1400 \text{ Hz}$; Xe–F_{ax} distance = 177 pm and $^1J[^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{eq}}] = 159 \text{ Hz}$; Xe–F_{eq} distance = 190 pm], and XeOF_3^+ [$^1J[^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{ax}}] = 464 \text{ Hz}$; Xe–F_{ax} distance = 188 pm and $^1J[^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{eq}}] = 1012 \text{ Hz}$; Xe–F_{eq} distance = 182 pm].

The only ^{129}Xe – ^{17}O couplings reported are those for XeOF_5^- (566 Hz), XeOF_4 (692–704 Hz), XeOF_3^+ (619 Hz), and XeO_2F_2 (521 Hz). For isoelectronic and structurally related species, a comparison of the reduced coupling constants $^1K(\text{Xe}, \text{F})$ and $^1K(\text{Xe}, \text{O})$ for axial Xe–F and Xe=O bonds in XeOF_4 (152.5–155.1) and XeF_5^+ (42.80–48.00) and for the equatorial Xe–F and Xe=O bonds in XeO_2F_2 (114.8) and XeOF_3^+ (13.78–14.73), all in units of $10^{20} \text{ N A}^{-2} \text{ m}^{-3}$, is consistent with the formal bond orders of Xe–F and Xe=O bonds in these species. The ^{129}Xe – ^{17}O coupling of XeOF_5^- (566 Hz) is significantly smaller than the $^1J(^{17}\text{O}, ^{129}\text{Xe})$ coupling in XeOF_4 and XeOF_3^+ (viz., 692–704 Hz

and 619 Hz, respectively) which may be a consequence of the more polar bonds in the anion.

Other one-bond coupling constants which have been reported include $^1J[^{129}\text{Xe(II)}, ^{15}\text{N}]$, $^1J[^{129}\text{Xe(II)}, ^{14}\text{N}]$, and $^1J[^{129}\text{Xe(II)}, ^{13}\text{C}]$. Their reduced coupling constant ranges, expressed in units of $10^{20} \text{ N A}^{-2} \text{ m}^{-3}$, are $^1K[\text{Xe(II)}, \text{N}] = 27.0$ to 142 and $^1K[\text{Xe(II)}, \text{C}] = 9.3$ – 14.3 , and are substantially smaller than $^1K[\text{Xe(II)}, \text{F}]$ values, which range from 176.2 – 228.9 .

Two-bond couplings, $^2J(^{129}\text{Xe}, ^{13}\text{C})$, have been observed for the Xe(II) cations, $\text{FXeN}\equiv\text{CH}^+$ and $\text{FXeN}\equiv\text{CCH}_3^+$. Pentafluorooxotellurate derivatives of xenon in its +2, +4, and +6 oxidation states exhibit $^2J(^{129}\text{Xe}, ^{125}\text{Te})$ couplings and have nonoverlapping ranges which depend on the oxidation state of xenon, but which are in the opposite direction to those observed for $^1J(^{129}\text{Xe}, ^{19}\text{F})$; $^2J(^{129}\text{Xe}, ^{125}\text{Te})$: Xe(VI) > Xe(IV) > Xe(II), with $^2J(^{129}\text{Xe}, ^{125}\text{Te}) = 470$ – 540 Hz for Xe(II), 988 – 1192 Hz for Xe(IV), and 1281 – 1856 Hz for Xe(VI). The reduced two-bond xenon–chalcogen coupling in FXeOSeF_5 is $^2K(\text{Xe}, \text{Se}) = 20.52$ is significantly less than the equivalent coupling in FXeOTeF_5 , $^2K(\text{Xe}, \text{Te}) = 44.8$ – 51.4 , both in units of $10^{20} \text{ N A}^{-2} \text{ m}^{-3}$. Inclusion of relativistic corrections⁶⁹ gives values of 17.77 and 31.1 – 35.7 ; the difference may be a reflection of the anticipated higher electronegativity of the OSeF₅ group relative to that of the OTeF₅ group implied from the ordering of the Xe(II) chemical shifts for FXeOSeF_5 and FXeOTeF_5 and for $\text{Xe}(\text{OSeF}_5)_2$ and $\text{Xe}(\text{OTeF}_5)_2$ (Table 1).

A number of three-bond ^{129}Xe – ^{19}F couplings have been observed for xenon and are associated with the Xe–C-bonded perfluorinated alkenyl and aryl cations of Xe(II) and the OSeF₅ and OTeF₅ derivatives of xenon in its +2, +4, and +6 oxidation states. While $^3J(^{129}\text{Xe(II)}, ^{19}\text{F})$ couplings in OTeF₅ and OSeF₅ derivatives are uniformly smaller than in Xe(IV)- and Xe(VI)OTeF₅ derivatives, there is less consistency among three-bond couplings than among one-bond and two-bond couplings with xenon. The relative magnitudes of three-bond couplings in the $\text{XeN}=\text{SF}_4^+$ cation and OTeF₅ and OSeF₅ derivatives differ considerably because the coupling paths differ. This is illustrated by xenon coupling to the equatorial fluorines of the OTeF₅ groups in the series $\text{O}=\text{XeF}_{4-n}(\text{OTeF}_5)_n$ (50 – 55 Hz) and to the two axial fluorines environments in the $\text{XeN}=\text{SF}_4^+$ cation (129 and 202 Hz) which have coupling paths with dihedral angles of 0° or 180° , whereas the paths to the axial fluorines in OTeF₅ groups (0 – 4 Hz) and to the equatorial fluorines in the $\text{XeN}=\text{SF}_4^+$ cation (~ 0 Hz) involve a dihedral angle of 90° . The only reported xenon–proton spin–spin coupling is $^3J(^{129}\text{Xe}, ^1\text{H})$ in the $\text{FXeN}\equiv\text{CH}^+$ cation.

Examples of a four-bond and a five-bond coupling have been observed between Xe(II) and the *meta*- and *para*-fluorines of the aromatic ring in the $\text{C}_6\text{F}_5\text{Xe}^+$ cation.

2.4 Solvation and Temperature Effects

Large temperature and solvent effects are observed for ^{129}Xe chemical shifts and ^{129}Xe – ^{19}F spin–spin couplings. Solvation effects probably result from coordination of the solvent in the xenon valence shell and show an overall decrease with decreasing number of electron lone pairs (increasing number of substituents).⁷ Thus, Xe(II) species exhibit the

greatest sensitivity to medium and temperature effects among the xenon oxidation states. The sensitivity of the $^{129}\text{Xe(II)}$ chemical shift to the effects of temperature and solvent is exemplified by XeF_2 , which shifts over a 400 ppm range, and by $\text{Xe}(\text{OTeF}_5)_2$, which shifts over a range of 200 ppm depending on the solvent, temperature, and concentration. In CH_3CN , XeF_2 exhibits a linear dependence with temperature and a slope $\Delta\delta(^{129}\text{Xe})/\Delta T = -0.4718 \text{ ppm K}^{-1}$ compared with a considerably smaller and opposite trend for the ^{19}F chemical shift, $\Delta\delta(^{19}\text{F})/\Delta T = 0.0042 \text{ ppm K}^{-1}$, over the same temperature range (240 – 320 K).⁶⁷ The chemical shift range of Xe(0) is in excess of 300 ppm in the pure gaseous, liquid, and solid phases, and in organic solvents and clathrates. The chemical shift of XeF^+ has been shown to be particularly sensitive to solvent composition. For $\text{XeF}^+\text{Sb}_2\text{F}_{11}^-$ dissolved in $\text{HSO}_3\text{F}/\text{SbF}_5$ solvent mixtures of variable composition, the shifts range from -574 ppm in pure SbF_5 to -911 ppm in pure HSO_3F solvents.³⁷ The interaction is presumed to arise by formation of a labile Lewis acid–base complex with a solvent oxygen or fluorine electron pair, which may be described in terms of structures II and III, and is understood in terms of the rationale described earlier (see Section 2.1).

There are also large solvent and temperature effects on spin–spin couplings involving xenon. For example, in XeF^+ , values of $^1J(^{129}\text{Xe(II)}, ^{19}\text{F})$ range from 6703 Hz in pure HSO_3F (-70°C) to 7210 Hz in pure SbF_5 (25°C).⁴⁵ For FXeOSO_2F in HSO_3F solvent, values of $^1J(^{129}\text{Xe(II)}, ^{19}\text{F})$ range from 6051 Hz (-100°C) to 5975 Hz (-84°C), and in BrF_5 solvent from 5530 Hz (-77°C) to 5848 Hz (-40°C). The couplings of the axial and equatorial fluorines to xenon in the XeF_5^+ cation show large temperature and solvent dependences; $^1J(^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{ax}}) = 1512$ Hz and $^1J(^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{eq}}) = 143.1$ Hz in SbF_5 (35°C) solvent compared with $^1J(^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{ax}}) = 1357$ Hz and $^1J(^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{eq}}) = 175.0$ Hz in HSO_3F (-90°C) solvent.⁶⁴ The temperature variation of $^1J(^{129}\text{Xe(VI)}, ^{19}\text{F}_{\text{eq}})$ for XeF_5^+ has been studied in detail for XeF_5^+ in HSO_3F solvent and is found to range from 193.8 Hz at -80°C to 149.9 Hz at 60°C .⁶⁴

When making comparisons of xenon couplings and chemical shifts, care must be taken to compare values that have been obtained under the same temperature and solvent conditions. Thus careful measurements of the ^{129}Xe chemical shifts of XeF^+ and XeOTeF_5^+ in SbF_5 solvent at 26°C and those of XeF_4 and $\text{Xe}(\text{OTeF}_5)_4$ in CFCl_3 at 24°C yield $\delta(\text{XeF}^+) - \delta(\text{XeOTeF}_5^+) = 898$ ppm and $\delta(\text{XeF}_4) - \delta[\text{Xe}(\text{OTeF}_5)_4] = 828.9$ ppm, confirming that, although the OTeF₅ group possesses a very high effective group electronegativity, it is less than that of fluorine.³²

3 INTERMOLECULAR INTERACTIONS WITH NOBLE GAS NUCLEI

Intermolecular interactions among noble gas atoms ranging from the dilute gas, liquid to the solid phases have been studied by ^3He , ^{21}Ne , ^{83}Kr , ^{129}Xe , and ^{131}Xe NMR spectroscopy, and are manifested in the relaxation times and chemical shifts of these nuclides. The very large chemical shifts of ^{129}Xe and its sensitivity to intermolecular interactions allow it to be used as a van der Waals probe in other gases,^{66,73–76} organic solvents,^{77,78} liquid crystals,^{79–82} clathrates,^{83,84} and

zeolites.^{85–90} In addition, there have been ^3He NMR studies of intermolecular interactions of entrapped helium within fullerenes.²

3.1 Medium Shifts

The only noble gases to exhibit medium-induced chemical shifts are xenon and helium. Shifts in the resonance of enriched ^{21}Ne (51% enrichment) in liquid and solid neon between 23 K and 34 K are less than 1 ppm and could not be observed.⁹¹ Chemical shifts of krypton and xenon have been observed in the gas and condensed phases. The chemical shifts of ^{83}Kr , ^{129}Xe , and ^{131}Xe in the gas, liquid, and solid, as well as the deshielding effects of a second gas on the xenon chemical shift, are density proportional and have been reviewed and summarized by Schrobilgen,⁷ Jameson,⁸ and Cowgill and Norberg.⁹² The deshielding effects of infinitely dilute xenon in organic solvents have also been studied and range from -148 ppm in CH_3OH to -335 ppm in CH_2I_2 , and are found to be proportional to the refractive index of the organic solvent.^{77,78}

NMR spectra have been observed for the entrapped noble gas nuclides ^3He and ^{129}Xe . Helium-3 has been used as a probe for the magnetic shielding environment inside fullerene cavities for the endohedral compounds $^3\text{He}@\text{C}_{60}$ and $^3\text{He}@\text{C}_{70}$, providing the only example thus far of the application of ^3He NMR spectroscopy to a chemical problem.^{1,2} The ^3He nucleus is shielded by 6.4 and 28.8 ppm, respectively, relative to dissolved ^3He in 1-methylnaphthalene solvent. These shieldings are large, indicating significant diamagnetic ring currents in C_{60} and even larger ones in C_{70} . Altering the π -bonding structure of the fullerene through reaction produces substantial changes in the shieldings of entrapped ^3He .² Azomethine ylide additions of *N*-methylglycine to the double bonds of $^3\text{He}@\text{C}_{60}$ and $^3\text{He}@\text{C}_{70}$ result in *N*-methylpyrrolidine adducts and in significant changes in ^3He shieldings upon addition to one or two fullerene double bonds. The ^3He nuclei of the $^3\text{He}@\text{C}_{60}$ adducts are more shielded and occur at -9.4 ppm and at -10.9 and -12.3 ppm relative to dissolved ^3He for the mono-adduct and bis-adducts, respectively. In contrast, mono-adducts of $^3\text{He}@\text{C}_{70}$ are deshielded with respect to $^3\text{He}@\text{C}_{70}$ and are assigned to resonances at -23.8 and -27.9 ppm.

The very large chemical shift range of ^{129}Xe and its sensitivity to intermolecular interactions in the gas phase^{66,73–76} and in solution^{77,78} have made ^{129}Xe NMR spectroscopy an extensively used probe for the characterization of zeolites, polymers, and other microporous solids. A large number of studies have resulted in which the ^{129}Xe chemical shift is found to vary with zeolite pore size, loading, temperature, and channel dimensions, with cation and coadsorbed molecule distributions, with dispersed metal atoms, and water content.^{85–90} The estimation of zeolite pore sizes and the study of guest molecule distributions in zeolites by ^{129}Xe NMR spectroscopy are of major importance. Using ^{39}Ar as a model for intermolecular shielding, ab initio calculations indicate that the ^{129}Xe chemical shifts of individual Xe_n clusters and their temperature dependencies are largely due to Xe–Xe interactions, and the average chemical shifts observed for the xenon clusters arise from averaging of the ^{129}Xe shielding over the various cluster configurations.^{89,93,94} Using Grand Canonical Monte Carlo methods for the simulation of the distribution and ^{129}Xe

chemical shifts of individual Xe_n clusters in zeolite cages, the chemical shifts are quantitatively reproduced by making use of pairwise additive ab initio intermolecular shielding functions^{95,96} based on suitable scalings of ^{39}Ar functions.^{93,94}

3.2 Relaxation Times

Nuclear relaxation mechanisms among the noble gases are purely intermolecular and differ from noble gases that are chemically bound, which are dominated by intramolecular mechanisms. The spin–lattice relaxation times, T_1 , of the noble gases decrease with increasing gas density.

Spin–lattice relaxation times have been determined in the pure gaseous, liquid, and solid phases of ^3He ,^{97–99} ^{21}Ne (no gas phase measurements),⁹¹ ^{83}Kr ,^{92,100} ^{129}Xe ,^{101,102} and ^{131}Xe .¹⁰³ In the cases of the spin- $\frac{1}{2}$ nuclides, the relaxation of ^{129}Xe appears to be dominated by the spin–rotation mechanism in the transient Xe_2 molecule whereas ^3He relaxation is dominated by dipolar interactions. Relaxation of quadrupolar nuclides occurs by interaction of the nuclear quadrupole moment with electric field gradients arising from collisional deformations of the spherical atoms.^{104,105} The observed relaxation times vary by nearly a factor of 10^3 among the three quadrupolar nuclides, ^{21}Ne , ^{83}Kr , and ^{131}Xe ; $T_1 = 23.5$, 0.608, and 0.041 s for the liquid and $T_1 = 150$, 3.3, and 0.190 s for the solid, respectively. Spin–spin relaxation times (T_2) have also been measured for liquid and solid ^{129}Xe .¹⁰⁶

1 INTRODUCTION

The structure and dynamics of oxygen-containing compounds is a subject of widespread significance. Compared with ^1H , ^{13}C , ^{31}P , and ^{19}F NMR, however, ^{17}O NMR has received little attention.^{1–8} This neglect is not surprising since, of the naturally occurring oxygen isotopes, only ^{17}O possesses a nuclear spin ($I = \frac{5}{2}$). Due to its electric quadrupole moment ($Q_e = -2.6 \times 10^{-30} \text{ e m}^2$), its low natural abundance (0.037%), and the extremely low absolute sensitivity compared with that of ^1H (about 1.1×10^{-5}), the ^{17}O isotope is one of the more difficult nuclei to observe by NMR spectroscopy. It is, however, of great interest to use a nucleus such as oxygen that is located at strategic molecular sites and is directly involved in inter- and intramolecular interactions. The ^{17}O NMR parameters, i.e. isotropic shielding, principal elements of the ^{17}O shielding and electric field gradient tensors, and the transverse and longitudinal relaxation times, can be considered as excellent means of probing the structure, bonding, and dynamics of oxygen-containing compounds. Furthermore, recent advances in instrumentation, the extremely large chemical shift scale (which aids in the resolution of quadrupole broadened resonances), and the availability of ^{17}O enriched compounds have alleviated these difficulties; thus, an increased use of the ^{17}O NMR technique can be envisaged.^{9–11}

2 EXPERIMENTAL ASPECTS

2.1 The Case of ^{17}O Enrichment

The stringent requirements in studies of compounds at natural abundance are the high concentrations ($>0.1 \text{ M}$) and extensive signal averaging needed.¹² Recording of spectra can be greatly facilitated by the use of ^{17}O enriched samples (Figure 1). When using FT high field instruments and ^{17}O labeled compounds (^{17}O enrichment 10–40 atom %), concentrations of greater than 1 mM are desirable, depending on the linewidths. Synthesis involving oxygen isotopes tends to involve rather straightforward organic reactions. However, one caveat that should be kept in mind when contemplating the synthesis of an ^{17}O labeled compound is the expense

Figure 1 ^{17}O NMR spectra (48.8 MHz; 40°C) of N -[^{17}O]acetyl-L-proline.¹³ (a) 10% enrichment, 0.1 M in aqueous solution containing 1 M NaCl and $5 \times 10^{-5} \text{ M}$ EDTA; $T_{\text{acq}} = 12 \text{ ms}$, NS = 300 000, total experimental time = 1 h: (upper trace) normal spectrum; (lower trace) after a Gaussian-exponential resolution enhancement. (b) 1% enrichment, 0.1 M in methanol, $T_{\text{acq}} = 10 \text{ ms}$, NS = 200 000, total experimental time = 32 min, line broadening (LB) = 50 Hz. (c) 0.4 M natural abundance in acetone (the asterisk marks the carboxyl oxygen resonance); $T_{\text{acq}} = 5 \text{ ms}$, number of scans (NS) = 1 900 000, total experimental time $\approx 10 \text{ h}$, LB = 50 Hz; (d) 1% enrichment, 0.1 M in acetone; $T_{\text{acq}} = 10 \text{ ms}$, NS = 1 350 000, total experimental time $\approx 8 \text{ h}$, LB = 50 Hz. (Adapted by permission of The American Chemical Society from R. N. Hunston, I. P. Gerothanassis, and J. Lauterwein, *J. Am. Chem. Soc.*, 1985, **107**, 2654)

of the starting reagents. Simple modifications of existing reactions are required. For example, $^{17}\text{O}_2$, C^{17}O , or C^{17}O_2 , is added to evacuated systems, as opposed to more traditional procedures which involve bubbling through the reaction mixture. Recently, a comprehensive overview of ^{17}O enriched methods has been published.¹⁴

2.2 Referencing Techniques

As with many heteronuclei, a variety of reference compounds and referencing procedures (both internal and external) have been suggested for ^{17}O NMR. For diamagnetic solutions, an external standard in a combined use of two cylindrical cells has been recommended.¹⁵ Using this technique, doubly distilled water or 1,4-dioxane can be used as external reference. Both compounds have chemical shifts which are indistinguishable at 30–40 °C and their magnetic susceptibility correction is small (<0.6 ppm) relative to common organic solvents. However, H_2O has the disadvantage that its chemical shift varies with temperature (–3 ppm between 27 and 90 °C) due to cleavage of intermolecular hydrogen bonds (the same applies for D_2O in addition to an isotopic effect of –3 ppm).

2.3 Solvent (H_2O) Suppression

Perhaps the most straightforward approach to solvent suppression is the use of ^{17}O depleted water, provided of course that rapid ^{17}O exchange does not occur between solvent and solute.¹⁶ Further suppression can be achieved by exploiting the special relaxation properties of the solvent, by postexperiment data processing and by selectively exciting the whole spectrum apart from that of the solvent.¹⁷ A critical note on the usefulness of the selective excitation pulse sequences in ^{17}O NMR has recently been published.¹⁸

2.4 Acoustic Ringing

Observation of very broad resonances in NMR is a potential problem due to baseline distortions. The most severe of the baseline artifacts is that due to the transient response of the NMR probe, often referred to as ‘acoustic ringing’, caused by the generation of ultrasonic waves from the action of the rf pulse. In the last decade, several pulse sequences designed for the suppression of acoustic ringing have been reported, and the reader should consult a relevant review article for details.¹⁹ For experiments in solution, the extended spin echo sequence was found to be particularly useful, since it utilizes minimum pulse and preacquisition delay times. A closely related pulse sequence for experiments in the solid phase has also been suggested.²⁰

3 CHARACTERISTIC PARAMETERS

3.1 Chemical Shifts

3.1.1 Experimental Shielding Ranges: Empirical Correlations

A general pattern of ^{17}O shielding is shown in Figure 2. For compounds containing oxygen bonded only to carbon and/or hydrogen there is a clear correlation between the C–O π bond order and a high frequency shift.²¹ This type of correlation arises from the multiple bond term $\Sigma_{B \neq A} Q_{AB}$ in the Karplus–Pople equation.²² For bridging oxygen atoms, a strong deshielding is observed when the substituents R are replaced by π -accepting acyl substituents which introduce π

Figure 2 ^{17}O chemical shift ranges for different X–O bonds. (Adapted by permission of Plenum Press from W. McFarlane and H. C. E. McFarlane, in ‘Multinuclear NMR’, ed. J. Mason, 1987, Chap. 14)

character into the C–O bond of the bridging oxygen. Thus, bridging oxygen resonances in carbonates and esters appear at high frequency relative to the corresponding resonances in alcohols, ethers, and acetals. An even greater high frequency shift is observed for anhydrides, where bridging oxygen atoms are bonded to two π acceptors. If chemical shifts are assumed to depend linearly on π bond order, the chemical shift of about 600 ppm for aliphatic aldehydes (π bond order of about 1) relative to water (π bond of 0) implies a chemical shift of about 200 ppm for CO_3^{2-} (π bond order of $\frac{1}{3}$). The observed shift of CO_3^{2-} (192 ppm) is in agreement with this crude prediction, further supporting the general correlation between π bond order and shielding discussed above.²

In nitrogen-containing compounds, as in carbon compounds, chemical shift values are determined largely by π bonding effects.^{23–25} Bridging oxygen resonances are observed at even higher frequency in nitrates, where π bonding is appreciable. A lesser, but nonetheless significant, effect is observed for bridging oxygen atoms in nitrates. The most striking feature of the ^{17}O shifts observed for P–O bonds is the small chemical shift range (20–260 ppm) which cannot be related to P–O bond order in a straightforward fashion. However, ^{17}O resonances for nonequivalent oxygen atoms in phosphates and polyphosphates can be resolved and have been used in stereochemical and binding site studies.^{26–28} For S–O bonding, similar trends to those displayed by P–O bonds are observed. Modification of the π bond order in an X=O group due to substituents on X results in a decrease (or increase) in the net charge on X as the charge on oxygen increases (or decreases). The chemical shift variations experienced by the nuclei X and O are then opposite and roughly proportional to the ratio $\langle r^{-3} \rangle_{2\text{px}} / \langle r^{-3} \rangle_{2\text{pO}}$.²⁴ For a series of oxyanions and a series of C=O and N=O compounds a linear correlation has been found between $\delta(^{17}\text{O})$ and the variation in ΔE^{-1} .²⁹ A linear correlation exists between acetone chemical shifts and the first maximum of the $n \rightarrow \pi^*$ transition for acetone/water

solutions³⁰ and for acetone in different solvents.³¹ Similar trends have also been observed in a variety of substituted acetophenones;³² however, it was suggested that such trends may be fortuitous, since the transition energy depends upon the balance of several effects associated with both π donation and σ withdrawal.³³ From a study on a series of aliphatic ethers, a correlation between $\delta(^{17}\text{O})$ and the first ionization potential has been suggested.³⁴

Compounds containing oxygen–oxygen bonds and oxygen–fluorine bonds display large high-frequency shifts.^{35–37} The ability, therefore, of ^{17}O NMR to distinguish unambiguously between nonequivalent oxygen atoms has found application in several structural and mechanistic studies. The same applies to oxygen bonded to transition metals (see below). Empirical correlations were extended to diamagnetic transition metal anions of the general formula MO_4^{n-} , and theoretical calculations were carried out to show that the absolute magnitude was reasonable.²⁹

3.1.2 Theory of ^{17}O Chemical Shifts (see *Shielding: Overview of Theoretical Methods*)

3.1.2.1 Isolated Molecules. Ab initio calculations^{38,39} of ^{17}O nuclear shielding tensors have been reported for a variety of simple molecules such as H_2O , CH_3OH , $(\text{CH}_3)_2\text{O}$, H_2CO , CH_3CHO , HCONH_2 , and CO . The results are gauge dependent and in many cases vary considerably depending on the basis set used. Gauge independent ab initio results for H_2O and H_2CO indicate a ^{17}O shielding of 757.6, 860.3, or 858.8 ppm for H_2CO , with respect to H_2O , compared with the experimental result of 580–600 ppm. The calculated data represent a choice of three basis sets. Semiempirical INDO (intermediate neglect of differential overlap) calculations are numerically smaller than the experimental results, whereas the CNDO/S (complete neglect of differential overlap/S) calculations produce better overall agreement.^{40–43} This probably reflects an insensitivity of the INDO orbital energies to changes in the environment of the oxygen. By omitting those molecules and ions which have nitrogen directly bonded to oxygen the CNDO/S results gave a standard deviation of 30.6 ppm and a correlation coefficient of 0.98 compared with the experimental values. Analysis of the CNDO/S results demonstrates that the ^{17}O shielding differences of some carbonyl compounds are dominated by the lowest energy $n \rightarrow \pi^*$ transition. For the linear species CO , CO_2 , and NO_2^+ , the largest contribution to the paramagnetic part σ_p of the ^{17}O shieldings arises from the lowest energy $\sigma \rightarrow \pi^*$ transition. Similarly, for the bent ion NO_2^- the lowest energy $\sigma \rightarrow \pi^*$ transitions are dominant for the in-plane components of the shielding tensor, while the out-of-plane contribution is controlled by $\sigma \rightarrow \sigma^*$ transitions. In general, these ^{17}O shieldings are in reasonable agreement with the available experimental data, and in some cases are an improvement upon ab initio results. Analogous calculations employing a basis set of gauge dependent atomic orbitals within the CNDO/2 framework have been reported for ^{17}O shieldings in electrolyte solutions.⁴⁴ For ozone,⁴⁵ the use of localized molecular orbitals within the IGLO method (see *Shielding Calculations: IGLO Method*) allows the contributions to the total shielding to be partitioned into orbital contributions, so that the specific role played by the lone pairs on the atom in question and orbitals centered on neighboring atoms can be discerned.⁴⁶ The calculated shieldings for O_3

were found to be extremely large, highly anisotropic, and to differ from the experimental values by a factor of 2–3. The authors also noted that the paramagnetic contributions are mainly due to the lone pairs on the respective oxygen atoms, unlike the triatomic molecules CO_2 and FNO in which the paramagnetic contributions are mainly due to the bonds interacting with the antibonding π^* electrons and only to a limited extent to the lone pairs.

3.1.2.2 Solvent and medium effects. Recently, the effect of electrical polarization on the chemical shielding of carbon monoxide has been considered in detail.^{47,48} In addition, the relationship between the vibrational frequency and the shieldings for three different types of electrical environments—a uniform field, a field gradient, and an axial point-charge dipole—together with experimental ^{13}C and ^{17}O isotropic shieldings and vibrational frequencies for a range of carbon monoxide derivatives of heme proteins has been described. For each type of environment, the shieldings vary linearly with the vibrational frequency for a relatively wide range of frequency shifts.⁴⁸ This shows, in agreement with experiment,⁴⁹ that there is a linear relationship that is opposite for ^{13}C and ^{17}O .⁵⁰

The effects of solvents on the ^{17}O nuclear shielding of solute molecules may be categorized into hydrogen-bonding interactions and influences that arise from electronic interactions between the dipole moments of the solute and solvent molecules. Precise mathematical expressions are not available for many nonbonded interactions. Consequently, continuum models tend to be more popular for investigating solvent effects on NMR parameters. The most widely used of these, to date, is the solvaton model.⁵¹ By means of this model the solute–solvent interaction can be included in the paramagnetic screening contribution, and the solvent induced shift is proportional to $(\epsilon - 1)/2\epsilon$, where ϵ is the dielectric constant of the medium. Some sum-over-states (SOS) and finite perturbation theory (FPT) calculations of oxygen nuclear shieldings of several organic functional groups, as obtained using the solvaton model, predict increases in shielding as ϵ increases.^{50,52} An analysis of the various factors contributing to the paramagnetic term reveals that the increase in shielding arises from a concomitant decrease in $\langle r^{-3} \rangle_{2p}$ and an increase in the weighted average of the energies of the various transitions contributing to the paramagnetic term. The observed decrease in $\langle r^{-3} \rangle_{2p}$ is consistent with an increase in the average separation between the nucleus and its 2p electrons as the charge q increases. The increase in the weighted averaged of the transition energies is largely controlled by the increase in energy of the lowest $n \rightarrow \pi^*$ transition as the extent of solvation increases.

The shielding of the ^{17}O nuclei of several functional groups are quite sensitive to hydrogen-bonding interactions. From a theoretical standpoint the shielding may be considered by using the supermolecule approach. A good example is provided by formamide.⁵³ Ab initio calculations using GIAOs (gauge invariant atomic orbitals) within the FPT framework have been reported for formamide (FMA) in the presence of its first hydration shell. The ^{17}O shielding values reported for the complexes $\text{FMA}-(\text{H}_2\text{O})_2$ show that the shift observed when the oxygen atom is directly involved in the hydrogen bond is much larger than the one occurring when the water molecules are bound to the NH group. The variation was calculated to be to low frequency in both cases. This is in agreement with

^{17}O NMR experimental data on FMA and several amides in different solvents.

3.2 Indirect Spin Coupling Constants

Because of the breadth of ^{17}O resonances, only relatively large coupling constants can be measured, and hence the majority of those recorded refer to couplings from directly bonded nuclei. $^1J(\text{O,H})$ in water and alcohols has values close to 80 Hz.^{54–56} The $^1J(\text{P,O})$ couplings involving P=O groups cover a fairly wide range (145–210 Hz) and for a series of compounds of type OPX_3 ($\text{X} = \text{F}$ or O in OMe , $\text{X} = \text{N}$ in NMe_2 , and $\text{X} = \text{C}$ in Me) there is a consistent drop in coupling with decreasing electronegativity of X . This may be qualitatively attributed to the electronegative substituents removing electrons in outer orbitals from the phosphorus atom, leading to a greater effective atomic charge and hence stronger contact interaction between the phosphorus nucleus and the s orbitals. A finite perturbation theoretical treatment within the CNDO/2 formalism has reproduced the observed trends, but not the absolute values.⁵⁷ The oxygen atoms in P-OMe groups within phosphates give rise to a consistently smaller coupling constant, compared with P=O , of between 90 and 100 Hz; there is an indication of a considerably larger value for phosphites. The reduced coupling constants decrease with increasing atomic number of the central atoms along the isoelectronic sequence VO_4^{3-} , CrO_4^{2-} , and MnO_4^- .⁵⁸ The values of ^{17}O spin–spin couplings have been used to investigate H_3O^+ species.⁵⁹ The ^{17}O NMR spectrum revealed a perfect quartet with $J(\text{O,H}) = 107$ Hz. Furthermore, the effect of H/D substitution is evident in the ^{17}O NMR spectra of $\text{H}_2\text{O-D}_2\text{O}$ in CH_2Cl_2 . Thus, the species H_2O , HDO , and D_2O could be identified from coupling constants, without reference to chemical shift data.⁶⁰ 2J couplings are normally about an order of magnitude smaller than the corresponding directly bonded couplings.⁶¹ However, there seems to be a particularly favored coupling pathway from hydrogen to the ‘ether’ oxygen atom in HCOOR systems, which is probably associated with π bonding across the planar framework.

In some cases coupled resonances cannot be resolved into fine structure but exhibit a partially collapsed structure, depending on the rate of proton transfer. In such cases decoupling of the other nuclei can lead to reduced linewidths and information about coupling constants.

When a spin- $\frac{1}{2}$ nucleus is bonded directly to ^{17}O , the X nucleus will also be relaxed by virtue of its spin–spin coupling with ^{17}O . This has been termed ‘scalar relaxation of the second kind’. Such a line-broadening effect for ^{17}O in ^{31}P NMR has been used to locate the position of the ^{17}O label and to calculate the percentage enrichment of ^{17}O . In addition, it has made possible analysis of the configuration of (^{16}O , ^{17}O , and ^{18}O) phosphate monoesters and (^{16}O , ^{17}O , and ^{18}O) thiophosphates by ^{31}P NMR.^{62–64}

3.3 Nuclear Quadrupole Coupling Constants

The electrostatic interaction between the nuclear quadrupole electric moment Qe and the electric field gradient tensor eq_{ij} is the quadrupolar interaction. An appropriate reference axis system can be chosen to reduce this interaction to two values:⁴ the main component

$$\chi = e^2 q_{zz} Q / h \quad (1)$$

and the asymmetry parameter (dimensionless)

$$\eta = (e^2 q_{xx} Q - e^2 q_{yy} Q) / e^2 q_{zz} Q \quad (2)$$

where $|e^2 q_{zz} Q| > |e^2 q_{yy} Q| > |e^2 q_{xx} Q|$.

The χ values for ^{17}O may be calculated by computing the field gradient from molecular wavefunctions and using the nuclear quadrupole moment Qe . Only relatively small molecules have been studied. Thus the calculated χ value for CO using the GAUSSIAN 88 program at the 6-31G* level⁴⁹ (3.1 MHz) was found to deviate from the experimental value (~ 4.4 MHz) (the value of 3.9 MHz obtained from ab initio calculations⁴⁷ is in better agreement with the experimental value). Furthermore, it was shown that hydrogen bonding to HF results in a significant decrease in χ of about 0.7 MHz for the linear species $\text{CO} \cdots \text{HF}$.

Semiempirical methods of various degrees of sophistication have been used to compute electric field gradients. Within the framework of the Townes–Dailey theory, the three components of the field gradient can be related to the electronic populations in the orbitals describing the oxygen bonding and to eq , the field gradient created by an electron in a $2p$ atomic orbital (the contribution from the valence s electrons is neglected because of the spherical symmetry). More elaborate models incorporate hybridization of atomic orbitals into valence bonding and lone pair orbitals. Such studies include the determination of σ and π orbital populations for X-O bonds ($\text{X} = \text{C}, \text{N}, \text{P}, \text{or } \text{S}$).^{65,66}

The majority of experimentally determined χ and η values have been obtained in the solid state by the use of NQR spectroscopy; however, some have been determined by NMR measurements on powders or single crystals, where χ is small with respect to the NMR frequency. Quadrupole coupling constants have also been derived from the splittings in the ^{17}O spectra of molecules partially oriented in an electric field⁶⁷ or dissolved in a nematic liquid crystal.^{68,69} Detailed studies of polynuclear osmium carbonyl dynamics have been undertaken and together with ^{13}C measurements have provided estimates of the ^{17}O quadrupole coupling constants.⁷⁰ In molybdenum hexacarbonyl, the ^{95}Mo and ^{97}Mo linewidths gave the reorientational correlation time, which in turn made it possible to determine the χ values from the ^{17}O linewidth.⁷¹

Experimental χ values cover the range -8 to 17 MHz. The sign of χ is irrelevant to the NMR experiment, but from a theoretical point of view it gives information about the orientation of the field gradient. The experimental χ values for a series of compounds in the solid state that contain C=O , -O- , P-O , N-O , or S-O bonds show the following trends:⁶

1. For substituted nitrophenols, hydroxybenzaldehydes, and nitrobenzaldehydes, the χ values are nearly invariant with the electronic properties of the substituent, but are reduced by hydrogen bonding.
2. Strong hydrogen bonding reduces the χ values by as much as 2.6 MHz.

In summary, the following scale of χ values has been suggested:

The ^{17}O χ values for the terminal CO groups in metallocarbonyls were found to be 1–3 MHz, although values below 0.1 MHz have also been observed. It was suggested that increased $d\pi - p\pi$ back-bonding from the metal will increase electron density perpendicular to the C–O axis and so reduce the χ values.⁷²

3.4 Relaxation Properties (see *Relaxation Theory for Quadrupolar Nuclei*)

3.4.1 Relaxation in the Extreme Narrowing Condition

In isotropic systems and in the absence of chemical exchange, the T_1 and T_2 relaxation times are equal and are given by

$$1/T_1 = 1/T_2 = 3/125(1 + \eta^2/3)\chi^2 f(\omega, D) \quad (3)$$

where χ is the nuclear quadrupole coupling constant. The asymmetry parameter η varies from 0 to 1 and describes the deviation of the electric field gradient from axial symmetry. $f(\omega, D)$ is the correlation function, which depends on the rotational diffusion constant D and its relative orientation with respect to the principal axes of the field gradient tensor. When isotropic reorientation is assumed, $f(\omega, D)$ reduces to the single correlation time τ_c . If the resonance absorption is a Lorentzian lineshape, the linewidth at halfheight $\Delta\nu_{1/2}$ is a direct measure of the relaxation time, provided that unresolved indirect spin coupling is not present and that chemical exchange phenomena do not take place. From equation (3) it is clear that the product $\chi^2(1 + \eta^2/3)$ can be obtained from ^{17}O relaxation times if the correlation time governing the relaxation is known. The Debye formula allows only the determination of the correct order of magnitude of τ_c . More precise values of τ_c could be obtained from the relaxation of other nuclei, such as ^{13}C or other quadrupolar nuclei; however, one should be aware of possible anisotropic reorientations due to molecular tumbling.⁴

3.4.2 Relaxation Outside the Extreme Narrowing Condition

In this case, the decay of the longitudinal (M_1) and transverse (M_2) magnetizations is no longer exponential but may be written as a weighted sum of $I + \frac{1}{2}$ exponentials:⁷³

$$M_1(t) = M_1(\infty) \left\{ 1 - k \left[\sum_{i=1}^{I+1/2} C_{1,i} \exp(-R_{1,i}t) \right] \right\} \quad (4)$$

$$M_2(t) = M_2(0) \left[\sum_{i=1}^{I+1/2} C_{2,i} \exp(-R_{2,i}t) \right] \quad (5)$$

Figure 3 Longitudinal (a) and transverse (b) relaxation of spin- $\frac{5}{2}$ nuclei in the absence of chemical exchange. The upper plots show the normalized amplitudes $C_{1,i}$ and $C_{2,i}$ of the three exponential components as a function of $\omega_0 \tau_c$ (coefficients 2 and 3 are plotted on the expanded scale given to the right). The lower plots show the relaxation rates as a function of the same parameter. (Adapted by permission of The American Institute of Physics from T. E. Bull, S. Forsen, and D. L. Turner, *J. Chem. Phys.*, 1979, **70**, 3106)

where $\sum_{i=1}^{I+1/2} C_{j,i}$ and $k = 2$ for an inversion–recovery experiment. Furthermore, although equation (4) is valid for the total magnetization, the decays of the individual components will normally not be exponential and will also depend on the length of the monitoring pulse. Equations (4) and (5) cannot be solved analytically, but must be solved numerically for each value of $\omega_0^2 \tau_c^2$. Figure 3 illustrates the longitudinal and transverse relaxation of spin $I = \frac{5}{2}$ nuclei in the absence of chemical exchange. The longitudinal relaxation may be regarded as a single exponential, within the limits of experimental error, for all correlation times. Conversely, the transverse relaxation is governed by the three contributions and the weights of the different contributions have similar magnitudes for the longer correlation times. For values of $\omega_0^2 \tau_c^2 \ll 1$, the transverse relaxation is approximately a single exponential. In the slow motion limit the rapid decay of the third component at longer correlation times may allow analysis in terms of just two exponential terms.

In addition to nonexponential relaxation for quadrupolar nuclei under conditions of nonextreme narrowing, the NMR signal will also be modified by shift changes which have been termed ‘second-order dynamic frequency shifts’ (see *Quadrupolar Interactions and Dynamic Frequency Shift*). Although long recognized theoretically, the experimental demonstration of such a phenomenon is not straightforward, since the symmetry of the composite peak is in practice difficult to distinguish from small phase misadjustment and is thus usually overlooked. Furthermore, strongly relaxed transitions may decay so quickly as to be undetected if the instrument deadtime is too long. Expressions for the NMR bandsape for $I = \frac{5}{2}$ and $I = \frac{7}{2}$ nuclei have been derived, both in the presence and the absence of chemical exchange.⁷⁴ In the limit $\omega_0 \tau_c \gg 1$, the $m = \frac{1}{2} \rightarrow m = -\frac{1}{2}$ component will dominate the spectrum because it is much narrower than the other components. This narrow signal will be shifted

towards lower frequency with a value proportional to χ^2/ω_0 . Between these two limits the resonance will be more or less asymmetric, with an apparent shift to either high or low frequency depending on the values of ω_0 , τ_c , and χ . The ratio of the dynamic shift to the linewidth $\Delta\omega_d/\Delta\omega_{\frac{1}{2}}$ in this region depends only on ω_0 and τ_c .

3.4.3 Effects of Relaxation Mechanisms Other Than Quadrupolar

It is evident from Figure 3 that the linewidth of the narrow component decreases as τ_c increases in the slow motion limit, while the linewidths of the intermediate and broad components increase. However, the linewidth of the narrow component does not necessarily decrease as τ_c increases if the chemical shift anisotropy is large. Such behavior has been observed in studies of the temperature and magnetic field strength dependence of ^{17}O NMR spectra of myoglobin MbC ^{17}O samples.⁷⁵ For $\tau_c \simeq 14$ ns and $\sigma_{\parallel} - \sigma_{\perp} = 800$ ppm (which is the value for a model heme compound obtained from NMR studies in the solid state) a CSA contribution to the linewidth of about 100 Hz was obtained for the narrow components. This value is comparable to that of the pure quadrupolar contribution to the linewidth (about 96 Hz). The CSA contribution to T_1 was found to be negligible (about 170 ms).

4 SELECTED APPLICATIONS

4.1 Dynamic and Kinetic Studies

Numerous dynamic and kinetic studies have been performed using ^{17}O NMR. Lineshape analysis is not straightforward because the linewidth itself is temperature dependent. Nevertheless, it has been shown that dynamic ^{17}O NMR is a convenient alternative to ^{13}C NMR for studies of metal carbonyl compounds.⁷⁶ A solution of $\text{HFeCO}_3(\text{CO})_{12}$ at -89°C gives only two ^{13}CO signals in a ratio of 1:2 instead of the expected four signals with a 1:1:1:1 ratio. In ^{17}O NMR, the four signals are easily observed at -11°C and a two-step exchange process averages all the sites, producing a single line at 108°C .

^{17}O NMR has been used to measure the rate of oxygen exchange in aldehydes and ketones,⁷⁷ cobaloximes,⁷⁸ and the periodate–water system.⁷⁹ It is possible to measure either the decay of a signal from a group enriched in ^{17}O or the growth of a signal that is undergoing exchange with ^{17}O labeled water.³

A substantial number of publications has been concerned primarily with studies of the hydration of ions in solution. The ^{17}O chemical shift of water molecules bound to Al^{3+} was found to be about 11 ppm to high frequency. Temperature dependence studies and lineshape analysis yielded the ^{17}O nuclear relaxation rates of the bound and free water molecules, the coordination number, and the rates of exchange between the bound and free water.⁸⁰ In addition, the thermodynamic parameters for activation characterizing the exchange reaction can be obtained. In cases where the chemical shift between ‘bound’ and ‘free’ water molecules is small, leading to overlapping of resonances, the resonance of the ‘free’ molecule can be shifted by adding small amounts of a paramagnetic salt.

Estimates of 4, 6, and 6 for the hydration numbers of $\text{Be}(\text{II})$, $\text{Al}(\text{III})$, and $\text{Ga}(\text{III})$ were obtained from area measurements. An alternative method of determining hydration numbers, by evaluating the magnitude of the shift of the water resonances caused by the dissolved paramagnetic ion, has also been suggested.⁸⁰

There is an extensive literature on ^{17}O NMR studies of the exchange rates of water molecules bound to paramagnetic ions.^{81–84} In this case there is a much greater chance of observing separate resonances from ^{17}O nuclei in ‘bound’ water molecules in the solvation shells of paramagnetic cations than in the corresponding diamagnetic cations. The magnitudes and temperature dependences of the linewidths (or relaxation time measurements) of the ‘bound’ and ‘free’ resonances, and the chemical shift separations between these resonances, can in principle be used to derive information about the hyperfine splitting constant, a_N , the rate of the solvent interchange process, T_e , and the solvation number. However, because the shifted resonance of the solvated water molecules is also often very broad, it is rarely possible in practice to derive the hydration number of the paramagnetic cation from straightforward area measurements. In such cases the hydration numbers may be obtained by using the theory developed by Swift and Connick⁸⁵ who investigated a variety of systems. This type of work and the chemical significance of the results have been reviewed (see *Paramagnetic Relaxation in Solution*).⁸⁶

4.2 ^{17}O NMR and Torsion Angle Effects

^{17}O NMR spectroscopy is a powerful method for detecting steric effects in molecules in which the steric interactions are characterized by the rotation of functional groups about single bonds to relieve van der Waals interactions or in rigid systems in which the steric interactions are partially accommodated by bond angle and bond length distortions.⁸⁷ ^{17}O deshielding is expected when the rotation leads to greater double bond character or reduced electron density on oxygen (e.g. in an isolated carbonyl group). Shielding, however, is observed in the situation in which the carbonyl group assumes more single bond character or increased density on the oxygen atom. Studies of such steric effects have been done on aromatic and heteroaromatic nitro compounds, aryl ketones, aldehydes and 1,2-diketones, aromatic carboxylic acids, esters and amides.^{88–91} For nitro aromatic compounds, a quantitative relationship was established between $\delta(^{17}\text{O})$ of the nitro group and the torsional angle between the aromatic ring and the nitro group (Figure 4). It appears that the solid state conformational preference, and thus the angle, is in remarkably good agreement with the average angle determined in the solution state.

4.3 Hydrogen-Bonding Effects (see *Hydrogen Bonding*)

The use of ^{17}O NMR appears to be especially promising for studying hydrogen-bonding interactions, because of the large chemical shift range of the oxygen nucleus.^{92–94} The dominance of intramolecular hydrogen-bonding effects over substituent effects has been clearly demonstrated in acetophenones, benzaldehydes, and hydroxynaphthoquinones.^{32,95} In

Figure 4 Plot of the torsion angles (X-ray) between aromatic rings and nitro groups versus ^{17}O chemical shift data.⁸⁷ (Reproduced by permission of CRC Press, Inc., from D. W. Boykin and A. L. Baumstark, in ' ^{17}O NMR Spectroscopy in Organic Chemistry', ed. D. W. Boykin, 1991, Chap. 3)

amides and peptides,^{10, 93, 96–100} both long-range dipole–dipole interactions and specific hydrogen bonds at the amide oxygen atom induce significant and specific shielding of the ^{17}O nucleus. Thus the overall chemical shift change between an amide oxygen atom in the absence of hydrogen-bonding interactions in vacuum and one that is fully hydrated in aqueous solution is, very probably, over 95 ppm. There is a linear correlation between $\delta(^{17}\text{O})$ and $\nu(\text{CO})$, the infrared (IR) amide I stretching vibration, for different solvents which have varying dielectric constants and solvation abilities.¹⁰⁰ This demonstrates that both IR and ^{17}O NMR spectroscopy appear to be reflecting a similar type of electronic perturbation, i.e. hydrogen bonding and dipole–dipole solute–solvent interactions. Further studies include investigations of the hydration and intra- and intermolecular hydrogen bonding of the *cis/trans* peptide oxygen atoms in AcYOH and AcYNHMe (Y = Pro or Sar)^{13, 98} (Figure 1), protected dipeptides,⁹⁹ and peptide hormones.^{101–103}

4.4 Oxygen Bonded to Transition Elements (Polyoxometalates)

^{17}O NMR has been employed frequently in stereochemical studies of polynuclear, anionic oxo complexes (polyoxoanions) of the early transition elements in a variety of oxidation states.^{104–108} In spite of their structural complexity, these polyoxoanions often yield well resolved ^{17}O NMR spectra, since large chemical shifts are observed and samples may often be observed at elevated temperatures in nonviscous solvents. Furthermore, ^{17}O enrichment is easily obtained. A representative example is the $[\text{V}_{10}\text{O}_{28}]^{6-}$ species, the structure and spectrum of which are shown in Figure 5. Exchange of oxygen atoms in the complex ion with those of H_2^{17}O in aqueous solution showed that all the different oxygen sites could be identified separately by their shieldings. If an oxygen atom attached to n vanadium atoms is designated as OV_n , then the observed chemical shifts are: $\text{OV} \simeq 1150$; OV_2 (three different sites) $\simeq 900, 790$ and 760 ; $\text{OV}_3 \simeq 390$; and $\text{OV}_4 \simeq 65$ ppm. It can be seen that there is a systematic reduction in $\delta(^{17}\text{O})$ with an increase in the number of vanadium atoms to which the oxygen atom is bound. Other complex anions of the formula $[\text{M}_6\text{O}_{19}]^{n-}$, where M = Mo ($n = 2$), Nb

Figure 5 (a) The D_{2h} symmetrized structure of $\text{V}_{10}\text{O}_{28}^{6-}$. Small filled circles represent vanadium atoms and large open circles represent oxygen atoms. One member of each symmetry-equivalent set of atoms is labeled. (b–e) ^{17}O NMR spectra at 13.5 MHz of $\text{V}_{10}\text{O}_{28}^{6-}$ in H_2O . All spectra were measured at 25°C with total vanadium concentrations of 1.5–1.8 M. The asterisk labels the metavanadate resonance. (Adapted by permission of The American Chemical Society from W. G. Klemperer and W. Shum, *J. Am. Chem. Soc.*, 1977, **99**, 3544)

($n = 8$), or Ta ($n = 8$), show the same qualitative regularities in shielding, with $\text{OM} > \text{OM}_2 > \text{OM}_6$. These regularities have been interpreted as a correlation between increasing chemical shift and increasing π bonding from the metal to the oxygen in different sites. The regularities persist in the ^{17}O spectra of a variety of more complex anions of lower symmetry in which other metals or nonmetals are substituted within an $[\text{M}_x\text{O}_y]^{n-}$ framework. It should be noted that the resonances of oxygen nuclei in the highly symmetrical environments of the complex anions, e.g. OM_4 or OM_6 , are relatively sharp. This is to be expected because the field gradient at these positions will be zero or very small; hence the normally dominant quadrupolar relaxation mechanism will be very weak and the relaxation times correspondingly long.

4.5 Heme Proteins and Model Compounds—Substrate Binding to Enzymes

The ^{17}O NMR spectra of several heme model compounds in solution have been reported.^{11, 109–111} Two signals at about

Figure 6 ^{17}O NMR spectra (54.2 MHz) of the oxygenated compounds **a** (---) and **b** (—) with a preacquisition delay time $\Delta t = 50 \mu s$ and recorded in two steps with the carrier frequency on the absorption resonances. Maximum concentration $\approx 10^{-2} M$ in toluene solution. Concentration of 1,2-dimethylimidazole (1,2-Me₂Im) $\approx 5 \cdot 10^{-1} M$, $T = 297 K$, NS = 1 080 000 (LB = 1 kHz) and 350 000 (LB = 500 Hz) for the high- and low-frequency resonances, respectively. The arrow denotes the region of the resonance position of the terminal oxygen atom of the picket-fence porphyrin model, with excess 1-MeIm, and ether models in which no hydrogen bonding interactions are expected. (Adapted by permission of the Royal Society of Chemistry from I. P. Gerothanassis, B. Look, and M. Momenteau, *J. Chem. Soc., Chem. Commun.*, 1992, 598)

1750 and 2500 ppm were observed for the FeO₂ linkage (Figure 6). The data were interpreted as ruling out sideways triangular bonding in favor of an end-on angular bonding arrangement. The data were explained in terms of bonding models in which the electrons of the FeO₂ moiety are totally paired.

Analysis of the ^{17}O relaxation and chemical shift data of $C^{17}O$ ligated hemoproteins has provided information on both the structural and the dynamic properties of the heme group.^{49,75,112} Peroxidases are heme proteins with molecular weights of about 40–42 kDa that catalyze oxidations by hydrogen peroxide. They contain iron-protoporphyrin IX as a noncovalently bound prosthetic group. The ^{17}O NMR spectra of CO-horseradish peroxidase isoenzyme C (Figure 7) indicate a single hemoprotein $C^{17}O$ signal (at 358.3 ppm) below pH 10 and two separate signals at pH 10.5. The new signal, which was assigned with the alkaline form of CO-horseradish peroxidase isozyme C, is broader and at about 7 ppm to high frequency relative to that of the acidic form. A similar pH-dependent relationship of the chemical shift and linewidth was observed for CO-horseradish peroxidase isozyme A and CO-horseradish peroxidase isozyme C. It was concluded that CO-horseradish peroxidase isozyme C undergoes a transition between the acidic and alkaline forms.¹¹² However, unlike the case of CO-horseradish peroxidase isozyme A, the transition is slow on the NMR timescale (see *Oxygen-17 NMR: Applications in Biochemistry*).

4.6 Hydration of Proteins: Water Orientation in Lyotropic Phases and Bilayers

Water plays a fundamental role in the conformation and activity of biological macromolecules (see *Protein Hydration*).

Figure 7 Oxygen-17 NMR spectra of CO-horseradish peroxidase isozyme C (CO-HRPC); concentration, 1 mM in 50 mM phosphate buffer at 11.7 T; NS = 50 000–250 000, recycle time 100–150 ms, pulse width $38 \mu s$, LB = 100 Hz. A, B, and CO_{aq} denote the acidic form of CO-HRPC, the alkaline form of CO-HRPC, and free CO in solution, respectively. (Reprinted by permission of The American Society for Biochemistry and Molecular Biology from H. C. Lee, K. Cummings, K. Hall, L. P. Hager, and E. Oldfield, *J. Biol. Chem.*, 1988, **263**, 16 118)

^{17}O NMR studies have several advantages compared with 1H and 2H NMR for protein hydration:

1. The relaxation effect is large, permitting studies at low protein concentrations.
2. The ^{17}O relaxation in water is generally dominated by the quadrupolar mechanism.^{113,114} The intramolecular origin of the electric field gradient makes the quadrupolar interaction virtually independent of the molecular environment.
3. The ^{17}O relaxation is not affected by proton (or deuteron) exchange with protic residues in the protein. Only T_2 can be affected by exchange within a narrow pH range near neutrality.
4. Cross relaxation that contributes to 1H relaxation is unimportant for ^{17}O .^{115,116}

Variable field T_1 and T_2 relaxation time measurements of several proteins¹¹⁷ were interpreted in terms of two layers of

hydration having a reorientational correlation time of about 20 ps (about eight times slower than that of bulk water and independent of the nature of the protein). This rapid local motion has a small anisotropic component (corresponding to an order parameter of 0.06) which is averaged out by protein reorientation with a correlation time of the order of 10 ns.

Water molecules are important constituents of lyotropic phases and bilayers. In this case the molecular motions are strongly anisotropic and the quadrupolar interaction is not averaged out to zero and may be measured when it is small compared with the Zeeman interaction. Ordering of a water molecule results in a quadrupolar splitting which is related to the order parameter. It has been shown that important dynamic information can be obtained from ^{17}O linewidth data which complement the ordering results from ^2H NMR.¹¹⁸ (see *Amphiphilic Liquid Crystalline Samples: Nuclear Spin Relaxation* and *Liquid Crystalline Samples: Structure of Nonrigid Molecules*).

4.7 The Solid State

Under conditions of magic angle spinning (MAS) (see *Magic Angle Spinning*), the $(\frac{1}{2}, -\frac{1}{2})$ transition of quadrupolar nuclei with nonintegral spin does not depend on first-order quadrupolar interactions or on the effects of θ (the angle between B_0 and q_{zz}). The powder bandshapes depend upon second-order quadrupolar effects which do not eliminate the possibility of obtaining meaningful NMR spectra. In this case operation at very high magnetic fields will generally be most advantageous since the maximum second-order quadrupolar linewidth of the $(\frac{1}{2}, -\frac{1}{2})$ transition decreases linearly with the magnetic field.¹¹⁹ Typical results are those obtained for a range of oxides, oxyanions and high temperature oxide superconductors.^{120–122} For fosterite (Mg_2SiO_4), in which three crystallographically distinct oxygen sites were partly resolved, it was possible to determine the chemical shifts (61, 62, and 47 ppm), the quadrupole coupling constants (2.35, 2.35, and 2.7 MHz), and the electric field gradient tensor asymmetry parameters (0.2, 1.0, and 0.3) associated with each. From similar studies of silicate minerals and other compounds it was found that the χ values are related to the percentage ionic character of the bonds to oxygen.¹²⁰ It has also been found that VAS can be advantageous, especially for removing resonances arising from transitions other than $(\frac{1}{2}, -\frac{1}{2})$ (see *Variable Angle Sample Spinning*). Furthermore, it has been demonstrated that ^{17}O spins can be polarized by the ^1H spin system, as is done for ^{13}C in CP MAS.¹²³

^{17}O NMR studies on single crystals have the advantage, compared with studies on powders, that the complete principal components of the nuclear quadrupolar coupling constant and shielding tensors can be obtained and their orientation relative to the local molecular symmetry can be determined.¹²⁴

1 INTRODUCTION

A phase transition is a typical effect related to the collective behavior of a many-particle interacting system. Structural and magnetic phase transitions are the most common ones in solids, where in the structural phase transitions the interacting particles are the atoms and in the magnetic phase transitions the interacting entities are the atomic magnetic moments. In the ideal case of second-order phase transitions, very general statistical thermodynamic treatments are available based on macroscopic order parameters and response functions.¹ The onset of the order parameter (i.e. when it first becomes nonzero) below the transition temperature T_c marks a spontaneous symmetry breaking while the enhancement and the slowing down of its fluctuations around T_c is reflected in the critical behavior of the appropriate response function. The above characteristics are universal and largely independent of the microscopic details of the system. This universality makes the investigation of phase transitions an important chapter in physics.

NMR and Nuclear Quadrupole Resonance (NQR) measurements, both of static and dynamic parameters, provide valuable insights into the local properties at phase transitions. In these techniques, the nucleus is used as a probe of the electric and magnetic hyperfine interactions in the system at the microscopic level. A resonance experiment is normally related only indirectly to the static and dynamic properties of the system and, thus, a reliable theoretical interpretative model is necessary for analyzing the experimental data.

In Sections 2 and 3, we discuss some general properties of static and dynamic critical phenomena at second-order magnetic phase transitions and at reversible, weakly first-order, structural phase transitions.

In Sections 4 and 5, we give some representative examples of NMR/NQR investigations in model systems, while in Section 6, we give an example of an NMR study at a strongly first-order phase transition where the general thermodynamic treatment is not applicable. The material covered in this article

assumes that one is familiar with the main aspects of the hyperfine interactions that couple the nuclear system to the ‘lattice’ in solids giving rise to the NMR/NQR lineshape, shift, and relaxation phenomena. Cross references to articles in this Encyclopedia where these interactions are treated are given in Section 7.

2 STATIC AND DYNAMIC CRITICAL PHENOMENA

The interpretation of NMR and NQR effects at phase transitions in solids is conveniently carried out in terms of local critical variables, $y(\mathbf{r}_1, t)$. The macroscopic order parameter is related to the time average of $y(\mathbf{r}_1, t)$ by

$$\eta \propto \sum_1 e^{i\mathbf{q}_c \cdot \mathbf{r}_1} \langle y(\mathbf{r}_1, t) \rangle \quad (1)$$

where $\mathbf{q}_c$ represents the periodicity of the ordering in the local critical variable. For a ferromagnet, $\mathbf{q}_c = 0$ and η is the spontaneous magnetization. For an antiferromagnet $|\mathbf{q}_c| = \pi/a$ and η is the sublattice magnetization (a = lattice parameter). For structural phase transitions $y(\mathbf{r}, t)$ is an atomic displacement from the equilibrium position, whereas for order–disorder ferroelectric transitions, $y(\mathbf{r}, t)$ is the orientation of a permanent electric dipole. The temperature dependence of the average critical variable $\langle y_1 \rangle = \langle y(\mathbf{r}, t) \rangle$ and, thus, of the order parameter is given by a universal law:

$$\eta \propto \left(\frac{T_c - T}{T_c} \right)^\beta \quad (2)$$

where $\beta = 0.5$ in mean-field theories. Close to the transition, a nonclassical critical region occurs, in which the mean-field approximation fails. This region covers a temperature interval that depends on the range of the interaction driving the phase transition and on the lattice dimensionality. The value of β in the nonclassical critical region is largely independent of the nature of the microscopic forces, depending instead on the dimensionalities and on the symmetries of the system and of the critical variables.

The dynamic properties can be described in terms of the pair correlation function

$$G(\mathbf{r}, t) = \langle y(\mathbf{r}, t) y(0, 0) \rangle \quad (3)$$

and the dynamic structure factor

$$S(\mathbf{q}, \omega) = \int e^{i(\omega t - \mathbf{q} \cdot \mathbf{r})} G(\mathbf{r}, t) d^3r dt \quad (4)$$

which describes the spectrum of the collective fluctuations. The spectrum of the fluctuations is related to the imaginary part of the generalized susceptibility by the fluctuation–dissipation theorem:

$$S(\mathbf{q}, \omega) = \frac{2\hbar \text{Im } \chi(\mathbf{q}, \omega)}{1 - \exp(-\hbar\omega/k_B T)} \approx \frac{2k_B T}{\omega} \text{Im } \chi(\mathbf{q}, \omega) \quad (5)$$

The static structure factor

Figure 1 Sketch of the general temperature behavior of the order parameter η and of the conjugate response function χ at the transition temperature T_c for a second-order phase transition

$$S(\mathbf{q}) = \frac{1}{2\pi} \int S(\mathbf{q}, \omega) d\omega = k_B T \chi(\mathbf{q}, 0) = \langle |y_{\mathbf{q}}|^2 \rangle \quad (6)$$

gives the mean-square amplitude of the collective fluctuations. On approaching the critical temperature, in a second-order transition, the static response function $\chi(\mathbf{q}_c, 0)$ for a given critical wave vector $\mathbf{q}_c$ diverges, thereby reflecting the enhancement of the fluctuations of the collective variables. For a magnetic phase transition, the static response function is the uniform magnetic susceptibility (ferromagnet) or the staggered susceptibility (antiferromagnet). The slowing down of the fluctuations is reflected, instead, in the progressive increase of the low-frequency components of the normalized dynamic structure factor: $S(\mathbf{q}, \omega)/S(\mathbf{q})$ (Figure 1).

3 THE NMR AND NQR APPROACH

The coupling of the nuclei to the lattice by magnetic and electric quadrupole hyperfine interactions, is the key point that makes NMR and NQR useful tools for investigating phase transitions and critical phenomena.

The magnetic dipolar and transferred hyperfine interactions of the nucleus with the electronic moments allow one to investigate the magnetic phase transitions. We write:

$$\hat{\mathcal{H}}_{\text{SI}} = \gamma \hbar \hat{\mathbf{I}} \cdot \mathbf{B}(t) \quad (7)$$

where γ is the nuclear gyromagnetic ratio and $\mathbf{B}$ is an effective local magnetic field that can be, in general, time dependent. The time average value $\langle \mathbf{B}(t) \rangle$ is proportional to the local average magnetic moments in the substance. Therefore, the shift in the NMR resonance frequency due to $\langle \mathbf{B} \rangle$ can be used to measure the temperature dependence of the static uniform susceptibility, which is the critical response function for a ferromagnet. Below the ordering temperature T_c (or T_N), the spontaneous magnetization (or staggered magnetization) may induce a local field $\langle \mathbf{B} \rangle$ at the nuclear site that is large enough to perform a zero field resonance experiment (see **Zero Field NMR**). In this case, the NMR resonance frequency is proportional to the spontaneous magnetization and, thus, accurate measurements of the critical temperature behavior of the order parameter are possible in principle.

The fluctuation part of $\mathbf{B}(t)$, in equation (7), induces spin-spin and spin-lattice relaxation, which become useful

parameters for the study of electronic spin dynamics. The structural phase transitions, on the other hand, can be investigated by using the quadrupole moment, Q , of the nucleus as a probe of the internal electric field gradients generated by the atomic charge distributions (see **Quadrupolar Nuclei in Solids**). We write

$$\hat{\mathcal{H}}_Q = \sum_{\alpha\beta} \hat{Q}_{\alpha\beta} V_{\alpha\beta} \quad (8)$$

where $\hat{Q}_{\alpha\beta}$ are the quadrupole operators depending on the spin coordinates only and $V_{\alpha\beta}$ are the electric field gradient (EFG) components. If $\hat{\mathcal{H}}_Q$ is a small perturbation of the Zeeman Hamiltonian $\hat{\mathcal{H}}_Z$, then the quadrupole interaction, equation (8), induces splittings and/or shifts of the NMR resonance line and also nuclear relaxation. On the other hand, if $\hat{\mathcal{H}}_Q$ is the dominant part of the total nuclear Hamiltonian, the resonance frequency is determined by the quadrupole interaction (NQR). In this case, the effect of the fluctuations of the EFG tensor is, in general, more complicated because it may also involve the modulation of the eigenstates of the main Hamiltonian.

The measurement of the static quadrupole interaction corresponds to the measurement of the time-average local EFG components. Since the EFG is related to the position in the lattice of the nuclear and electronic charges, one can measure atomic displacements and/or changes of the electronic charge density which are, in turn, related to the order parameter of structural phase transitions (see **Field Gradients and Their Application**).

Regarding the dynamic properties, one can relate the nuclear spin-lattice relaxation rate T_1 and the nuclear spin-spin relaxation rate T_2 quite generally to the dynamic structure factor defined in equation (4), which contains the information about the critical dynamics of the system. Whenever the weak collision theory of nuclear relaxation is applicable, the relaxation rate can be expressed in terms of the spectral densities $J_\alpha(\omega_\alpha)$ at ω_α of the correlation functions for ‘appropriate’ lattice functions $F_L^\alpha(t)$:

$$T_i^{-1} = \sum_{\alpha} C_{\alpha}^i J_{\alpha}(\omega_{\alpha}) \quad (i = 1, 1\rho, 2, 1d) \quad (9)$$

where the coefficients C_{α}^i depend on the nucleus and on the relaxation mechanism: $i = 1$ corresponds to the spin-lattice relaxation in the laboratory frame; $i = 1\rho$ to the one in the rotating frame; $i = 2$ to spin-spin relaxation; and $i = 1d$ to the dipolar relaxation (see **Relaxation: An Introduction**).

If we focus our attention on the contribution to relaxation due to fluctuations of the critical variable V_1 , we can expand the lattice functions:

$$F_L^\alpha(t) = \sum_1 A_1^\alpha V_1(t) \quad (10)$$

The above expansion is exact for certain types of system and it is only an approximation in other cases. Note that we have simplified the notation for the critical variable with respect to the notation in equations (1) and (3) by setting $y(\mathbf{r}_1, t) = V_1(t)$. By introducing collective variables $V_{\mathbf{q}}(t)$ through a Fourier transformation

$$V_q(t) = \frac{1}{\sqrt{N}} \sum_1 V_1 e^{iq \cdot r_1} \quad (11)$$

we can rewrite the spectral densities in terms of the dynamic structure factor as

$$\begin{aligned} J_\alpha(\omega_\alpha) &= \frac{1}{N} \int e^{-i\omega_\alpha t} \sum_q \sum_{11'} A_1^\alpha A_{1'}^\alpha e^{iq \cdot r_{11'}} \langle V_q(0) V_{-q}(t) \rangle dt \\ &= \sum_q \mathcal{A}_q^\alpha S(q, \omega_\alpha) \end{aligned} \quad (12)$$

The q summation reflects the fact that the relaxation rates are local quantities. The q components of $S(q, \omega)$ are weighted by the $\mathcal{A}_q^\alpha$ factor because the relaxation rates involve, in general, both auto and pair correlation functions for the local critical variable at the l and l' sites. The presence of the ‘filter’ factors $\mathcal{A}_q^\alpha$ in equation (12), has the disadvantage of complicating the relationship between T_l^{-1} and $S(q, \omega)$. On the other hand, if an explicit expression for the form factors $\mathcal{A}_q$ can be obtained from theoretical considerations, one can achieve direct information on the symmetry and on the correlation properties of the fluctuations, as will be shown in Section 5. Further details about the NMR/NQR approach to the study of phase transitions are to be found in Borsa and Rigamonti.²⁻⁴

4 ORDER PARAMETER STUDIES

4.1 Structural Phase Transitions

As an example of an investigation of the temperature dependence of the order parameter in a structural phase transition, we consider the ^{39}K NMR study of KMnF_3 .⁵ In the perovskite-type crystal KMnF_3 , a weakly first-order, reversible transition from cubic to tetragonal phase occurs at $T_c = 186$ K. The transition involves rotations of the MnF_6 octahedra in the opposite sense in adjacent (001) planes perpendicular to the c axis, as shown in Figure 2. This deformation corresponds to the freezing-in of the R_{25} mode of vibration at the R point of the Brillouin zone (i.e. $q = \pi/a, \pi/a, \pi/a$). The generalized order parameter can be assumed to be given by the average rotation angle $\langle \phi_1 \rangle$ in a given cell l . For a uniform transition at T_c , all rotation angles are identical, i.e., $\phi_l = \phi$, where ϕ is the order parameter. Potassium-39 has a quadrupole moment $Q = 0.07$ barns. In the cubic phase, no quadrupole effects are present. In the tetragonal phase ($T < T_c$), a nonzero EFG tensor arises at the ^{39}K site. The tensor has axial symmetry with $Z \parallel C$ and asymmetry parameter $\eta = (V_{xx} - V_{yy})/V_{zz} = 0$. The size of the resulting quadrupole coupling constant $\chi = eQV_{zz}/h$ (QCC) can be measured from the second-order shift of the central line transition ($\frac{1}{2} \leftrightarrow -\frac{1}{2}$) in a single crystal. The shift for $I = \frac{3}{2}$ is

$$\frac{\Delta B}{B_0} = \frac{\Delta \nu}{\nu_0} = -\frac{3\nu_Q^2}{16\nu_0^2} (1 - \cos^2 \theta)(9 \cos^2 \theta - 1) \quad (13)$$

where θ is the angle between $\mathbf{B}_0$ and the Z axis of the EFG tensor, and $\nu_Q = eQV_{zz}/2h$. From a simple calculation of the

Figure 2 Perovskite structure of ABX_3 crystals. The atomic displacements corresponding to rotations of BX_6 octahedra in the opposite sense in adjacent planes are shown in the Figure with arrows. These rotations correspond to the R_{25} mode of vibration at the R point of the Brillouin zone. Its freezing is responsible for the cubic-to-tetragonal phase transition in KMnF_3 , SrTiO_3 , and RbCaF_3 . ($\square$) A; ($\circ$) B; ($\bullet$) X

EFG tensor in terms of a point ion charge approximation, one finds that $V_{zz} \propto \phi^2 \propto \epsilon^{2\beta}$. Therefore, the measurement of the QCC amounts to the measurement of the square of the order parameter. The experimental results are shown in Figure 3.

From the analysis of the temperature dependence of the quadrupole coupling constant, it could be concluded that for $\epsilon = (T_c - T)/T_c > 10^{-1}$ the molecular field approximation (MFA) is valid and the critical exponent is $\beta = \frac{1}{2}$. For $\epsilon < 10^{-1}$, nonclassical critical effects are present and the critical exponent crosses over to a value close to $\beta = \frac{1}{3}$. Since $\beta = \frac{1}{3}$ describes nonclassical critical effects in isotropic three-dimensional magnetic systems and in fluids, the above result is an elegant confirmation of the universality of critical effects at phase transitions. Other examples of studies of order parameter at structural phase transitions by NMR can be found in Rigamonti.³

4.2 Magnetic Phase Transitions

A very successful application of the NMR technique to the investigation of the critical behavior of the order parameter was performed in the antiferromagnet MnF_2 .⁶ In this sample the ^{19}F nuclei are strongly coupled to the nearest neighbor Mn^{2+} magnetic moments. This circumstance allows one to make precise measurements of the local internal field at the ^{19}F site by measuring the corresponding zero field NMR frequency. Actually, the measurements were performed in a single crystal with an applied magnetic field $\mathbf{B}_0$, and the zero field frequency

Figure 3 Temperature dependence of the ^{39}K quadrupole coupling constant in KMnF_3 . (a) The linear T dependence of $eQV_{zz}/h \propto \phi^2 \propto \epsilon^{2\beta}$ is indicative of $\beta = 0.5$; (b) the linear T dependence of $(eQV_{zz}/h)^{3/2} \propto \phi^3 \propto \epsilon^{3\beta}$ for $T \rightarrow T_c$ is indicative of $\beta = \frac{1}{3}$

$\nu_0(T)$ was derived from analysis of the ^{19}F NMR composite spectrum. The temperature dependence of $\nu_0(T)$ is a measure of the temperature dependence of the staggered magnetization $M_{\text{st}}(T)$ which, in turn, represents here the order parameter. A best fit of $\nu_0(T)/\nu_0(0) = M_{\text{st}}(T)/M_{\text{st}}(0) = (1 - T/T_c)^\beta$ yields a critical exponent $\beta = \frac{1}{3}$ with a very high degree of accuracy. The determination of β by NMR in MnF_2 remains one of the most accurate experiments in this field.

It is not always possible to measure the internal local field with good precision and close enough to T_c to get a reliable value for the critical exponent β . In most cases, one is limited to the study of the temperature dependence of the spontaneous magnetization well below T_c , or to the measurement of the overall temperature behavior to be compared with mean field theories. Even so, the NMR technique offers a very useful tool of investigation.

As further examples of order parameter studies, we present, in the following, results obtained in magnetic systems, which are the ceramic materials from which high- T_c superconductors evolve upon appropriate doping: $\text{YBa}_2\text{Cu}_3\text{O}_6$ ⁷ and $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ ⁸ (see *High Temperature Superconductors*). $\text{YBa}_2\text{Cu}_3\text{O}_6$ is a planar Heisenberg antiferromagnet with $T_N = 420$ K. Two different Cu sites are present. The one of interest here is the Cu site in the magnetic bilayers, which experience both a quadrupole coupling to the nonzero EFG and a Zeeman interaction with the hyperfine field generated by the Cu^{2+} atomic magnetic moments. For $T < T_N$ the internal field dominates and the zero field spectrum can be analyzed in terms of a central transition ($+\frac{1}{2} \leftrightarrow -\frac{1}{2}$) and two satellite

Figure 4 Copper-63 zero field antiferromagnetic spectrum in $\text{YBa}_2\text{Cu}_3\text{O}_{6.05}$ at 200 K, obtained by plotting the echo intensity vs. frequency of the irradiating radiofrequency field

($\pm\frac{3}{2} \leftrightarrow \pm\frac{1}{2}$) transitions whose resonance frequency is given by:

$$\nu_{1/2, -1/2} = \nu_0 \left[1 + \frac{3}{16} \left(\frac{\nu_Q}{\nu_L} \right)^2 \right] \quad (14a)$$

$$\nu_{\pm 3/2, \pm 1/2} = \nu_0 \left[1 \mp \frac{1}{2} \left(\frac{\nu_Q}{\nu_L} \right) \pm \frac{3}{64} \left(\frac{\nu_Q}{\nu_L} \right)^3 \right] \quad (14b)$$

A typical zero field spectrum at $T < T_N$ is shown in Figure 4, where a total of six lines are discernible: three lines for each of the two Cu isotopes (63, 65) according to equations (14a) and (14b). The fit of the spectrum at different temperatures to equations (14a) and (14b) allows one to derive the temperature dependence of $\nu_0(T) = \gamma B_I$, which is a measure of the internal magnetic field $B_I(T)$ and, thus, of the staggered magnetization $M_{\text{st}}(T)$, since $\nu_0(T)/\nu_0(0) = B_I(T)/B_I(0) = M_{\text{st}}(T)/M_{\text{st}}(0)$ (see Figure 5). The results were compared with the predictions of spin-wave theory.⁷

Another example of order parameter study is provided by the ^{139}La NQR in $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$.⁸ The lanthanum cuprate system is a planar Heisenberg antiferromagnet with $T_N = 320$ K for $x = 0$ and a Neel temperature that decreases rapidly on increasing Sr substitution, whereby, for $x = 0.02$, $T_N \sim 0$. The ^{139}La nucleus, $I = \frac{7}{2}$, has an NQR spectrum above T_N , centered at about 19 MHz (for the $\frac{7}{2} \leftrightarrow \frac{5}{2}$ transition). When the temperature is lowered below T_N , an internal magnetic field arises at the La site, generating the splitting of the NQR resonance line, as shown in Figure 6.

The distance between the two peaks of the NQR spectrum is proportional to the projection of the local internal field B_z , on the direction z of the EFG tensor: $\Delta\nu = 2\gamma B_z$. Thus,

Figure 5 Temperature dependence of the ^{63}Cu nuclear resonance frequency in its internal local field below T_N . The solid line is a best fit curve discussed in Bucci et al.,⁷ which gives the reduction of the order parameter upon increasing temperature due to the thermal excitation of spin waves

Figure 6 Lanthanum-139 NQR spectrum in zero external magnetic field in the ordered antiferromagnetic state. The NQR resonance line corresponds to the $\pm\frac{5}{2} \leftrightarrow \pm\frac{3}{2}$ transition. The doublet originates from the Zeeman splitting due to the internal magnetic field. The spectrum is obtained by plotting the echo intensity at different operating frequencies

a measurement of the separation of the two NQR lines is proportional to the internal field and, thus, is proportional to the spontaneous, staggered magnetization below T_N . The results are shown in Figure 7. From the departure of the experimental points at low temperatures and for $x \neq 0$, from the behavior predicted by the MFA expression, it was possible to derive information about the effect of Sr doping on the magnetic properties of the system (for details, see Chou et al.⁸).

Figure 7 Zeeman splitting $\Delta\nu$ of the ^{139}La NQR line (see Figure 6 plotted vs. temperature for samples of $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ having a different content of Sr. The full lines are the behaviors predicted for the temperature dependence of the order parameter in the MFA

5 CRITICAL DYNAMICS STUDIES

From equations (9) and (12), one can derive a general relationship connecting the NMR relaxation rate T_i^{-1} to the dynamic structure factor $S(\mathbf{q}, \omega)$:

$$\frac{1}{T_i} = \sum_{\alpha} \sum_{\mathbf{q}} \mathcal{A}_{\mathbf{q}}^{\alpha} S(\mathbf{q}, \omega_{\alpha}) \quad (15)$$

As a general rule we can expect that, on approaching the transition temperature T_c from the high-temperature side, the fluctuations of the critical collective variable, $V_{\mathbf{q}}$, increase in amplitude for the critical wave vector $\mathbf{q}_c$ and the frequency of the fluctuations approaches zero for the same wave vector. As a consequence, the relaxation rate in equation (15), which is most sensitive to the fluctuations at low frequency ($\omega_{\alpha} = 0$ for a T_2 process and $\omega_{\alpha} \approx \omega_L$ for a T_1 process), should be strongly enhanced. However, since the relaxation rate is a local property, only the components of $S(\mathbf{q}, \omega_{\alpha})$ near $\mathbf{q}_c$ will contribute to the enhancement of T_i^{-1} . Since a given nucleus is coupled to many neighboring critical variables (i.e. electronic spins in magnetic systems or atoms in structural transitions), the coupling parameter $\mathcal{A}_{\mathbf{q}}^{\alpha}$ in equation (15) is, in general, a function of $\mathbf{q}$. Thus, only if the coupling parameter is different from zero at $\mathbf{q} = \mathbf{q}_c$ can the NMR relaxation rate give information about the critical fluctuations near T_c . Here we present some representative examples of studies of the critical dynamics for $T \rightarrow T_c$ by means of NMR relaxation rate measurements.

5.1 Structural Transitions

The crucial role in the NMR/NQR investigation of structural phase transitions is the quadrupole coupling [equation (8)], which involves the dependence of the EFG tensor from the local critical variables $V_I(t)$. Let us consider a few representative examples of displacive-type phase transitions from the high-temperature cubic phase to the low-temperature

Figure 8 Experimental results for the spin—lattice relaxation rates of different nuclear probes in different crystals as a function of temperature. The broken vertical line represents the transition temperature T_c for the cubic—tetragonal structural phase transition

tetragonal phase in crystals having the ABX_3 perovskite structure depicted in Figure 2. The crystals considered are NaNbO_3 , RbCaF_3 , SrTiO_3 , and LaAlO_3 , and the nuclei investigated can be either the one occupying the A site or the one occupying the B site. In the above displacive transitions, the critical variables are the rotation angles $\phi_i(t)$ of the oxygen octahedra with respect to their untilted equilibrium positions (see Figure 2). The EFG tensor components can be expressed in this case in terms of a linear combination of the critical variables: $V_{\alpha\beta} = \sum_i A_{i\alpha\beta} \phi_i(t)$. The critical behavior of the nuclear spin—lattice relaxation rate, T_1^{-1} , in the crystals listed above, is illustrated in Figure 8. In some instances T_1^{-1} is strongly enhanced as $T \rightarrow T_c$, in other instances it is only weakly enhanced, and in two cases there is no enhancement at all. This represents a vivid demonstration of the role of the ‘filter’ parameter $\mathcal{A}_q$ in equation (15). In fact, the structural transitions considered in Figure 8, involve different symmetries of the critical wave vector q_c . For example, for NaNbO_3 , the rotational fluctuations are of M_3 symmetry, whereas in SrTiO_3 , the rotational fluctuations are of R_{25} symmetry, as in the case of KMnF_3 (see Figure 2). Thus, depending on the location in the lattice of the nucleus considered, and on the symmetry of the critical rotational fluctuations, the coupling parameter A_{q_c} can be either zero or different from zero and can have a different q dependence in the vicinity of $q = q_c$. Thus, according to equation (15), one can have different degrees of coupling to the critical fluctuations and, consequently, different degrees of enhancement. A detailed discussion of this subject can be found in Rigamonti.³

5.2 Magnetic Phase Transitions

A striking example of enhancement of NMR relaxation due to critical fluctuations is offered by the ^{19}F linewidth behavior in the antiferromagnet MnF_2 near T_N , as shown in Figure 9. Analysis of such an NMR linewidth experiment in MnF_2 , and more accurate data from FeF_2 , have yielded

Figure 9 Fluorine-19 NMR linewidth in MnF_2 vs. temperature. The critical broadening occurs in the vicinity of the antiferromagnetic ordering temperature $T_N = 67.4 \text{ K}$

valuable information about critical dynamic indices.⁶ In both MnF_2 and FeF_2 , the ^{19}F NMR line is broadened by the ‘lifetime’ effect. The lineshape is Lorentzian and the linewidth is proportional to T_2^{-1} , which in turn is equal to T_1^{-1} (the same situation as found in liquids!). The critical variable $\nu_1^\alpha(t)$ can be identified here, with the Mn^{2+} electronic spin component $s_1^\alpha(t)$. From equations (9) and (12), and by using the fluctuation–dissipation theorem, one has

$$\delta\nu_{\parallel} = \sum_q \mathcal{A}_q^{\parallel} S(q, 0) \propto k_B T \lim_{\omega \rightarrow 0} \int d^3q \mathcal{A}_q^{\parallel} \frac{\text{Im} \chi(q, \omega)}{\omega} \quad (16)$$

By assuming that the fluctuations at the critical antiferromagnetic wave vector, $q = q_{\text{AF}}$, dominate, by assuming a Lorentzian shape for the generalized susceptibility $\chi(q, \omega)$ with width $\Gamma_{\parallel}(q)$ and since $\mathcal{A}_{q_{\text{AF}}}$ is different from zero for the coupling of ^{19}F with the three Mn^{2+} nearest neighbor spins, one finds⁶

$$\delta\nu_{\parallel} \propto \frac{\chi(q_{\text{AF}})}{\Gamma_{\parallel}(q_{\text{AF}})} \xi_{\parallel}^{-3} \quad (17)$$

where $\Xi_{\parallel}$ is the correlation length for the longitudinal spin correlation function. From the general theory of critical phenomena,¹ one has

$$\chi(q_{\text{AF}}) \propto \varepsilon^{-\gamma}, \quad \xi \propto \varepsilon^{-\nu}, \quad \Gamma_{\parallel}(q_{\text{AF}}) \propto \xi^{-z} \propto \varepsilon^{+\nu z} \quad (18)$$

with $\gamma = \nu(2 - \eta)$, leading to

$$\delta\nu_{\parallel} \propto \varepsilon^{-n} \quad [n = \gamma - 3\nu + \nu z = \nu(z - \eta - 1)] \\ \times \left(\varepsilon = \frac{T - T_N}{T_N} \right) \quad (19)$$

The value obtained from fitting the linewidth data in FeF_2 is $n = 0.67 \pm 0.02$, which has allowed the author to infer that the dynamic critical index z should be about 2.0, since $\gamma = 2\nu = \frac{4}{3}$ and $\eta \sim 0$. Just the same as for the studies

of the order parameter, one should point out that only in a very few special cases is it possible to perform a study of the critical dynamics from NMR with the high accuracy that was possible in FeF_2 . One of the main reasons is that in most cases it is impossible to separate the contributions to the relaxation from the different components of the order parameter. Nevertheless, interesting information about the critical dynamics can be obtained, as is illustrated by the ^{37}Cl NMR study in $\text{Sr}_2\text{CuO}_2\text{Cl}_2$.⁹ $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ is a layered perovskite with body-centered tetragonal K_2NiF_4 structure. The Cu^{2+} spins form a two-dimensional (2D) Heisenberg system with antiferromagnetic (AF) coupling which orders at $T_N = 260$ K. The structure and the magnetic properties of $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ are similar to those of La_2CuO_4 , which is the precursor of an important family of high- T_c superconductors.

The ^{35}Cl nuclear spin-lattice relaxation rate, $T_1^{-1} \equiv 2W$, displays a sharp peak at $T_N = 260$ K due to the enhancement and the slowing down of the AF fluctuations of the correlated Cu^{2+} spins (see Figure 10). From equations (9) and (12) one has

$$\begin{aligned} \frac{1}{T_1} &\equiv 2W = \sum_{\mathbf{q}} \mathcal{A}_{\mathbf{q}} S(\mathbf{q}, \omega_L) \\ &= \frac{1}{2} \gamma^2 \frac{1}{N} \sum_{\mathbf{q}} |\mathbf{B} \cdot \mathbf{q}|^2 \int \langle s_{\mathbf{q}}^+(0) s_{\mathbf{q}}^-(t) \rangle dt \quad (20) \end{aligned}$$

where we have expressed the ‘filter’ parameter $\mathcal{A}_{\mathbf{q}}$ in terms of the effective local field $\mathbf{B}(t)$ at the nuclear site as defined in equation (7). Since the Larmor frequency ω_L is small compared with the electron-spin fluctuation frequency, we set $\omega_L = 0$; also, the dynamic structural factor $S(\mathbf{q}, \omega)$ has been expressed in terms of the correlation function of the transverse (with respect to the applied field) spin components $s^{\pm}(t)$, which act as the critical variables. By assuming, as is done for the case of MnF_2 , an exponential decay of the spin correlation function, with decay rate $\Gamma(\mathbf{q})$ we can write

$$\frac{1}{T_1} = \gamma^2 \sum_{\mathbf{q}} |\mathbf{B} \cdot \mathbf{q}|^2 \frac{|s_{\mathbf{q}}|^2}{\Gamma(\mathbf{q})} \quad (21)$$

Since the hyperfine field at the ^{35}Cl site does not cancel for an AF arrangement of the Cu^{2+} spins, one expects the main contribution to the ^{35}Cl relaxation rate to come from AF fluctuations. By expanding the $\mathbf{B} \cdot \mathbf{q}$ factor around $\mathbf{q} = \mathbf{q}_{\text{AF}}$ and by using dynamic scaling arguments¹⁻⁴ for the $\mathbf{q}$ dependence of the inplane correlated fluctuations, equation (21) becomes

$$\frac{1}{T_1} = (\gamma B_{\text{eff}})^2 \frac{1}{N} \sum_{\mathbf{q}} \frac{\xi^{2-\eta} f(q\xi)}{\omega_e \xi^{-z} g(q\xi)} \quad (22)$$

where B_{eff} is the static field at the ^{35}Cl site for the AF configuration of Cu^{2+} spins and ω_e is the fluctuating frequency for the uncorrelated Cu^{2+} spins coupled by the exchange constant J , i.e., $\omega_e = \frac{8}{3} J^2 n S(S+1)/\hbar$. In equation (22), we have written $|s_{\mathbf{q}}|^2$ in terms of the correlation length Ξ (in lattice units) and $\Gamma(\mathbf{q}) = \omega_e/\Xi^z g(q\xi)$, where z is the dynamic scaling exponent and $f(q\xi)$, $g(q\xi)$ are homogeneous functions of the product $x = q\xi$.¹ By transforming the $\mathbf{q}$ summation in equation (22) into a 2D

Figure 10 (a) Enhancement of the ^{35}Cl nuclear spin—lattice relaxation in $\text{Sr}_2\text{CuO}_2\text{Cl}_2$ in the vicinity of the antiferromagnetic ordering temperature $T_N = 260$ K. (b) Log—log plot of the relaxation rate vs. $\epsilon = (1 - T/T_N)$ used to determine the critical exponent n

integral and taking into account the convergence of $\int f(x)/g(x) dx$ to a number of the order of unity one has

$$\frac{1}{T_1} = 2W = (\gamma B_{\text{eff}})^2 \frac{1}{\omega_e} \xi^{z-\eta} \quad (23)$$

The critical divergence of $1/T_1 \equiv 2W$ for $T \rightarrow T_N^+$ is of the form $2W \propto (T - T_N)^{-n}$ with $n = 1.2 \pm 0.1$ as shown in Figure 10. This critical divergence is close to the one observed in the ^{19}F NMR linewidth in the 2D Heisenberg model system K_2MnF_4 .^{10,11} Since $\Xi \propto (T - T_N)^{-\nu}$ one has $n = \nu(z - \eta)$.

As one can see, the critical exponent n for the divergence of the relaxation rate is different for the 2D system ($\text{Sr}_2\text{CuO}_2\text{Cl}_2$)

and the 3D one (FeF_2). In the latter case, $n = \nu(z - \eta - 1)$ was derived [see equation (19)]. The difference is associated with the different integration in q space due to the different lattice dimensionality D . Furthermore, the critical indices ν , z , and η are expected to be different in the two above-mentioned magnetic systems as a consequence of the different lattice dimensionality (2D vs. 3D) and the different spin dimensionality (Heisenberg vs. Ising) leading to the different values of n in the two cases.

6 UNCONVENTIONAL PHASE TRANSITIONS

The NMR studies discussed up to this point are focused on the critical static and dynamic behavior near the transition temperature of second-order or weakly first-ordered phase transitions in solids. However, the NMR technique has also been applied widely to study phase transitions that are not amenable to the general thermodynamic treatment of second-order transitions and related to critical effects in model systems. For example, important information was obtained by NMR in the study of first-order structural phase transitions, order–disorder transitions with diffusion, semiconductor–metal phase transitions, metal–superconductor phase transitions, etc. To illustrate one of these applications, we report here the ^{113}Cd NMR study of the martensitic transformation in Ag–Cd alloys.¹²

Several noble metal-based and Ni-based metallic alloys near the equiatomic concentration display a diffusionless structural phase transformation from a high-temperature body-centered cubic structure (austenite) to a compact structure (martensite). The transformation is strongly first order and belongs to the class of the *martensitic phase transformation* (MPT). It takes place by macroscopic nucleation of martensitic regions at the temperature M_S and proceeds on lowering the temperature by the growth of the martensite within the austenite matrix until the sample is fully transformed at a temperature M_F . If the transformation is thermoelastic, the two phases coexist at thermal equilibrium at any temperature in the interval between M_S and M_F and the transformation is reversible with a small hysteresis. NMR studies of MPTs have established that the Knight shift on any nucleus in the alloy is slightly, but significantly, different in the austenitic compared with the martensitic phase. This is due to small changes of the symmetry of the conduction-electron wavefunction and/or of the density of states at the Fermi level in the two phases. Based on this circumstance, one can investigate the relative proportion of martensite over the austenite within the temperature interval of the thermoelastic transformation. Let us consider the MPT of equiatomic Cd–Ag alloy with $M_S = 144\text{ K}$ and $M_F = 120\text{ K}$. The coexistence of two signals, centered at different frequencies, is evident in the ^{113}Cd NMR spectra shown in Figure 11.

A quantitative evaluation of the fraction of martensite present in thermoelastic equilibrium at each temperature can be obtained by the deconvolution of the adsorption line in the two components. The procedure requires some precautions and some assumptions which are discussed in detail in Rubini et al.¹² The results for the fraction of martensite as a function of the temperature are reported in Figure 12.

It should be stressed that the NMR method allows one to monitor the absolute quantity of martensite present and

Figure 11 Cadmium-113 NMR spectrum in the Ag–Cd alloy at $B_0 = 7$ tesla for different temperatures: (a) $T > M_S$, (b) $M_F < T < M_S$, (c) $T < M_F$. The coexistence of two signals from the two phases is clearly visible in case (b)

thus can detect residual parts of the sample that remain untransformed or continue to transform slowly even below M_F . In this respect, NMR proves to be complementary to dynamic measurements, such as resistivity or differential thermal analysis, which are based on the detection of relative changes of the characteristics of the whole system. For example, one can observe a small discontinuity in the growth curve in Figure 12 around the liquid nitrogen temperature (77 K). This is due to the fact that the sample was cycled several times from room temperature down to 77 K in order to stabilize the thermoelastic MPT. The ‘memory’ of the system to the cycling procedure is an aspect of the interesting shape memory effects associated with the MPT.

1 INTRODUCTION

With the discovery of the phenomenon of NMR in bulk samples in 1945, a new, powerful, analytical method became available to chemists. The ^{31}P nucleus was among the first nuclei to which NMR spectroscopy was applied. Phosphorus-31 spectroscopic data have been in the literature since 1951,^{1,2} and their number increased rapidly in the following years. In 1967 the first comprehensive compilation of ^{31}P NMR data of simple phosphorus compounds, as well as a presentation of the current theory of phosphorus chemical shifts, was published.³ Another publication⁴ and a review⁵ cover the literature up to 1969 and to mid-1982, respectively.

With the development of pulse Fourier transform NMR spectroscopy the sensitivity of the spectrometers improved and the ^{31}P NMR experiment became routine. As a consequence the amount of published ^{31}P NMR data increased dramatically. By 1987 it was estimated that more than 40 000 ^{31}P NMR data items were available in the literature. A 'Handbook of ^{31}P NMR Data' contains extensive compilations of representative data, including coupling constants, for all types of phosphorus compounds.⁶ More data can be found in a series of books dedicated partially^{7,8} or entirely^{9–11} to ^{31}P NMR. A number of reviews^{12–14} dealing with the application of ^{31}P NMR to transition metal complexes with phosphorus ligands, and a review¹⁵ describing the main developments in ^{31}P NMR of transition metal–phosphine complexes in the period 1970–1977, are available.

With modern spectrometers and using all instrumental and relaxation aids phosphorus compounds at 200 ppm and even 5 ppm concentration levels can be detected by ^{31}P NMR.⁹ Due to this capability, ^{31}P NMR spectroscopy has also gained importance as an analytical tool in biology and medicine. The work in this area is documented by a series of reviews^{16–21} and books.^{22,23}

2 NUCLEAR PROPERTIES AND STANDARDIZATION

The important properties of the ^{31}P nucleus for NMR spectroscopy are given in Table 1. Since phosphorus compounds are generally reactive, no suitable internal reference compound

Table 1 Properties of the ^{31}P Nucleus^{7,8,10}

Natural abundance, C (%)	100
Nuclear spin, I	$\frac{1}{2}$
Magnetic moment, μ (μ_N)	1.1316
Magnetogyric ratio γ ($10^7 \text{ rad T}^{-1} \text{ s}^{-1}$)	10.8394
NMR frequency at 2.35 T (MHz)	40.480
Receptivity relative to that of ^1H , D^P	6.63×10^{-2}
Receptivity relative to that of ^{13}C , D^C	3.77×10^2

is available for general use. Phosphorus-31 chemical shifts are referenced to 85% aqueous H_3PO_4 as an external standard. According to the present sign convention shifts are given positive for signals appearing at higher frequency (lower field) with respect to that of the standard. Great care is recommended, however, when using data from the older literature, since there was a change in sign convention in the mid-1970s.

A disadvantage of 85% H_3PO_4 as a standard is its broad resonance signal. A number of secondary external standards, giving much sharper signals, are therefore in use: P_4O_6 ($\delta^{31}\text{P} = 112.5$), $\text{P}(\text{OMe})_3$ ($\delta^{31}\text{P} = 140.4$), $\text{PO}(\text{OMe})_3$ ($\delta^{31}\text{P} = -2.4$), $[\text{P}(\text{OH})_4]\text{ClO}_4$ ($\delta^{31}\text{P} = -0.1$), $\text{Na}_2[\text{CH}_2(\text{PO}_3\text{H})_2]$ in D_2O ($\delta^{31}\text{P} = 16.7$), $(\text{NEt}_4)_2\text{HPO}_4$ in H_2O ($\delta^{31}\text{P} = 2.1$).^{8,9} In some cases D_3PO_4 ($\delta^{31}\text{P} = 0.3$) and $(\text{CH}_3)_3\text{PO}$ ($\delta^{31}\text{P} = 72.6$) are used as internal standards.^{8,9} Alternatively the ^2H internal lock signal can be used to obtain accurate chemical shifts referenced to $\text{Si}(\text{CH}_3)_4$ or to an idealized shift for 85% H_3PO_4 . However, there is little agreement on Ξ for 85% H_3PO_4 with values ranging from 40 480 720 to 40 480 754 Hz.^{7,9} An absolute ^{31}P shielding scale is based on gas phase measurements of PH_3 .²⁴

Normally the reported ^{31}P chemical shifts are not corrected for diamagnetic susceptibility. In addition temperature, solvent, and concentration dependence of $\delta^{31}\text{P}$ for both the reference compound and the compounds under study, may be important. Thus variations in reported chemical shifts for the same compound of up to ± 10 units can be encountered in the literature.^{7–10}

Measurements of the nuclear Overhauser enhancement show a wide variation extending from zero to the theoretical maximum of 124%.^{8,10,25}

Spin–lattice relaxation times T_1 of phosphorus compounds vary mostly between 1 and 30 s and can depend strongly on solvent, temperature, and concentration. Compilations of T_1 data for simple phosphorus compounds are found in Mason,⁸ Verkade and Quin,⁹ and Berger et al.¹⁰ Typical values are ~ 1.3 s for RPH_2 , 3–9 s for $\text{P}(\text{OR})_3$, 3–6 s for PX_3 ($X = \text{halogen}$), 2–9 s for $[\text{R}_4\text{P}]\text{X}$, 10–31 s for R_3P , 6–30 s for $\text{PO}(\text{OR})_3$, and 2–11 s for R_3PO .⁹ For a number of three-coordinated phosphorus compounds the spin rotation mechanism has been shown to account for T_1 at ambient temperature, while at low temperatures dipolar contributions become important.⁸ However, $\text{P}_2t\text{-Bu}_4$ relaxes by a dipolar mechanism even at ambient temperature. Going to four-coordination the relative contribution of the spin rotation mechanism decreases and is still important in the five-coordinated species $\text{PCl}_n\text{Ph}_{5-n}$ ($n = 2–4$) and the PF_6^- ion. A rare example, in which chemical shift anisotropy plays an important role in relaxation, is represented by Ph_3PO .⁸

3 EXPERIMENTAL TECHNIQUES

Due to its favorable nuclear properties ($I = 1/2$, high NMR frequency and high receptivity), the ^{31}P nucleus is easy to observe and no particular instrumental equipment is required. Early ^{31}P NMR spectra of solutions were recorded on continuous wave instruments and were often poorly resolved. Now practically all data are obtained with modern FT NMR spectrometers, equipped either with multinuclear probes or with separate pretuned probes for ^{31}P observation, yielding highly resolved spectra with $\Delta\nu_{1/2}$ often below 1.0 Hz. The optimum pulse duration depends on the relaxation time T_1 of the ^{31}P nucleus and the acquisition time T_{ac} . It has been recommended to set the pulse duration at $\cos^{-1}(e^{-T_{\text{ac}}/T_1})$.²⁶ Routine ^{31}P NMR spectra are obtained with broadband proton decoupling using a rapid pulse repetition (1 s) and a short pulse angle (30°).

A large number of special experimental NMR techniques have been applied to the ^{31}P nucleus including spin tickling,⁹ selective²⁷ and broadband⁹ ^{31}P decoupling, SPT,⁹ COSY,⁹ reverse shift heterocorrelated NMR spectroscopy,^{9,28} homonuclear^{9,29} and heteronuclear^{9,30} J resolved two-dimensional NMR spectroscopy, EXSY,³¹ and Hahn-echo extended pulse sequences.³² The CP MAS technique is widely used to obtain solid state ^{31}P NMR spectra.^{9,33} Liquid crystal ^{31}P NMR spectra of several cyclopolyphosphines $(\text{RP})_n$ and of other trivalent and pentavalent phosphorus compounds have been reported.⁹ In a few cases reactions of phosphorus compounds have been studied by CIDNP.³⁴

For ^{31}P measurements at variable temperature a 0.1 M solution of triphenylphosphine and triphenylphosphine oxide in toluene- d_8 has been recommended as a shift thermometer. At an operating frequency of 40 MHz the change in $\delta^{31}\text{P}$ is 1.3 Hz per degree.³⁵

4 CHEMICAL SHIFTS

The range of ^{31}P chemical shifts for liquid, dissolved, or gaseous diamagnetic phosphorus compounds covers nearly 2000 ppm and extends from +1362 for $t\text{-BuP}[\text{Cr}(\text{CO})_5]_2$ to -552 for gaseous P_4 . If dissolved paramagnetic compounds are included, it widens to about 4700, with +3471 for the complex $[(\text{C}_4\text{Me}_4\text{P})_2\text{U}(\text{BH}_4)]_2$ on the high-frequency side and -1219 for $\text{OsCl}_4(\text{PBu}_2\text{Ph})_2$ on the low-frequency side.^{9,10} The characteristic ranges of $\delta^{31}\text{P}$ for one- to six-coordinated phosphorus compounds are shown in Figure 1. For pentavalent phosphorus the shift ranges are relatively narrow, and shielding of the phosphorus nucleus increases as its coordination number increases from 3 to 6. No such dependence is found for the trivalent phosphorus and, except for one-coordinated phosphorus compounds, the shift ranges are much wider.^{6,36} Detailed bar charts showing the dependence of $\delta^{31}\text{P}$ for individual classes of phosphorus compounds on the type of atoms bonded to phosphorus can be found in Tebbly⁶ and Mason.⁸

According to a semiempirical treatment proposed by Van Wazer and co-workers^{3,37} phosphorus chemical shifts can be interpreted in terms of three contributions: the bond angles at the phosphorus atom, the electronegativity of the substituents, and the extent of π bonding. If only one parameter is being changed at a time, useful correlations

Figure 1 Typical ranges of $\delta^{31}\text{P}$ for differently coordinated phosphorus compounds

within a class of compounds are obtained.^{8,10} Thus for cyclopolyphosphines $(\text{RP})_n$ the phosphorus chemical shift is almost linearly correlated with the average endocyclic PPP bond angles, and definite ranges can be established for $n = 5$ ($\delta^{31}\text{P} = +50$ to -10), $n = 4$ ($\delta^{31}\text{P} = -50$ to -80), and $n = 3$ ($\delta^{31}\text{P} = -30$ to -180). The only known compound for $n = 6$, $(\text{PhP})_6$, ($\delta^{31}\text{P} = -22$) also fits this correlation.^{8,10} Linear shift/bond angle correlations have also been reported for the basal phosphorus atoms in cage molecules of the series $\text{P}_4\text{S}_x\text{Se}_{3-x}$ ($x = 0-3$), $\text{P}_y\text{As}_{4-y}\text{S}_3$, and $\text{P}_y\text{As}_{4-y}\text{Se}_3$ ($y = 0-4$)³⁸ and for differently substituted cyclotriphosphines.³⁹ For $\delta^{31}\text{P}$ of *tert*-phosphines an additive relationship for the alkyl substituents is found; deshielding of phosphorus increases in the order $\text{Me} < \text{Et} < i\text{-Pr} < t\text{-Bu}$.⁷ More additive relationships have been reported for $\delta^{31}\text{P}$ in polyphosphines P_nH_{n+2} ,⁴⁰ primary⁴¹ and secondary phosphines,⁴² and alkyl phosphonium salts.⁴² Additive relationships often fail, however, when π bonding or electronegative substituents are involved.^{7,8,10}

Theoretical calculations of ^{31}P chemical shifts for a series of simple phosphorus compounds by semiempirical methods and for PH_3 by ab initio methods have been reviewed.⁹ Using the IGLO method, ab initio calculations of $\delta^{31}\text{P}$ for larger molecules have also been performed.⁴³

Isotope effects on ^{31}P nuclear shielding caused by ^2H , ^{13}C , ^{15}N , ^{18}O , $^{34,36}\text{S}$, $^{35,37}\text{Cl}$, and $^{79,81}\text{Br}$ have been observed.^{44,45}

In 2-amino-1,3,2-dioxaphosphorinane 2-chalcogenides the isotopic effect of ^{15}N on $\delta^{31}\text{P}$ is larger for the shorter equatorial than for the longer axial P–N bond.⁴⁴

4.1 One-Coordinate Phosphorus

The range of ^{31}P chemical shifts for one-coordinated phosphorus compounds (phosphaalkynes $\text{R}-\text{C}\equiv\text{P}$ ^{6,36,46,47} and $[2,4,6-t\text{-Bu}_3\text{C}_6\text{H}_2-\text{N}\equiv\text{P}][\text{AlCl}_4]$ ⁴⁸) extends mainly from +96 to –70. Depending on R, shielding of the phosphorus nucleus in phosphaalkynes increases generally in the order $(\text{CH}_3)_3\text{Si} < \text{aryl}, \text{H} < \text{alkyl} < \text{amino} < \text{F}$.^{36,46} A linear relationship results for $\delta^{31}\text{P}$ and δN of identically substituted phosphaalkynes and nitriles.³⁶ Phosphorus-31 solid state NMR investigations of $2,4,6-t\text{-Bu}_3\text{C}_6\text{H}_2-\text{C}\equiv\text{P}$ ⁴⁹ and $[2,4,6-t\text{-Bu}_3\text{C}_6\text{H}_2-\text{N}\equiv\text{P}][\text{AlCl}_4]$ ⁵⁰ have been published.

4.2 Two-Coordinate Phosphorus

Compilations of $\delta^{31}\text{P}$ are available for the large number of two-coordinated phosphorus compounds.^{6,51–53} Values of $\delta^{31}\text{P}$ extend from +954 to –363 with most of them between +600 and –300. This wide shift range corresponds to a variation of phosphorus character from a phosphonium type with a high-frequency chemical shift to a phosphide type with a low-frequency chemical shift. The overall charge of the molecule seems not to be important.^{6,51} Values of $\delta^{31}\text{P}$ of fully unsaturated phosphorus heterocycles extend from +495 to –5 with most of the shifts between +300 and +50.^{6,36,52,53}

Linear correlations are found for $\delta^{31}\text{P}$ in aryl-substituted phosphaalkenes with Hammett constants and for $\delta^{31}\text{P}$ in iminophosphines with the $n \rightarrow \pi^*$ transition energies. Values of $\delta^{31}\text{P}$ of $=\text{PR}$ in various acyclic compounds and $\delta^{13}\text{C}$ and $\delta^{77}\text{Se}$ of the corresponding $=\text{CH}_2$ and $=\text{Se}$ compounds also give fair linear correlations. More linear correlations are found for the exchange of $=\text{P}$ –for $=\text{N}$ –in both acyclic and heterocyclic compounds and for $=\text{CH}$ –in otherwise identical heterocycles.³⁶

Solid state ^{31}P NMR spectra of a diphosphene,⁵⁴ a phosphaalkene,⁴⁹ and benzo-anellated heterophospholes⁵⁵ have been reported.

4.3 Three-Coordinate Phosphorus

The ^{31}P chemical shifts of three-coordinate trivalent phosphorus cover a wide range from +282 to –461 with most of the shifts between +220 and –290.⁶ Ranges of $\delta^{31}\text{P}$ for individual types of P (III) compounds are found in Tebbby,⁶ Mason,⁸ and Berger et al.¹⁰ Values of $\delta^{31}\text{P}$ of conformationally mobile di- and polyphosphines are likely to be temperature-dependent. In alkenic-substituted phosphines the ^{31}P nucleus is more shielded in the Z- compared with the E-isomer (effect of steric compression). A nearly linear correlation is found between $\delta^{31}\text{P}$ in $\text{Ph}_2\text{P}-\text{R}$ and $\delta^{13}\text{C}$ in CH_3-R .^{8–10}

For three-coordinate pentavalent phosphorus $\delta^{31}\text{P}$ ranges (excluding extreme values) essentially from +300 to +40 and is thus found at higher frequency than $\delta^{31}\text{P}$ of higher-coordinated phosphorus(V).^{6,36,56} In σ^3 -phosphoranes of the type $\text{R}-\text{PXY}$, depending on the double bonded substituents X and Y, phosphorus shielding generally increases in the order $\text{ML}_n < \text{S} < \text{Se} < \text{CR}_2 < \text{NR} < \text{O}$.^{36,56}

4.4 Four-Coordinate Phosphorus

The ^{31}P chemical shift range of pentavalent tetracoordinate phosphorus extends essentially between +140 and –90 with a few extreme values for phosphonium compounds of up to –308.⁶ Shift ranges for individual classes of compounds can be found in Tebbby,⁶ Mason,⁸ and Berger et al.¹⁰

A number of phosphonic and phosphinic acids, inorganic phosphates, and polyphosphates have been investigated by solid state ^{31}P NMR spectroscopy.¹⁰ In the case of polyphosphates, the different $\delta^{31}\text{P}$ values of the terminal and bridging phosphate groups have been interpreted in terms of the electronegativity difference between terminal and bridging oxygen atoms (estimated at 0.4) and the difference in π -bonding order.⁵⁷ A linear relationship results between $\delta^{31}\text{P}$ and the P–O bond strength in inorganic phosphates.⁵⁸

In phosphates and phosphate esters, as well as in their thio derivatives a clear dependence of $\delta^{31}\text{P}$ on the XPX angle (X = O, S) is observed. In phosphoric and phosphonic acids, and in mono- and dinucleotides the ^{31}P chemical shift shows a dependence on pH. Good linear Hammett correlations and a linear $\delta^{31}\text{P}/\delta^{13}\text{C}$ relationship for $[\text{Ph}_3\text{PR}]\text{X}$ and CH_3-R have been reported.¹⁰

In contrast to the tetracoordinate phosphorus(V), the ^{31}P chemical shift range for the tetracoordinate trivalent phosphorus (phosphoranide-type phosphorus) is much larger and extends from +222 to –242.⁶

4.5 Five-Coordinate Phosphorus

The chemical shift of five-coordinate phosphorus covers a range between +31 and –195 with the majority of shifts between 0 and –80.⁶ A temperature dependence of the NMR spectra is often encountered, due to intermolecular^{9,59} or intramolecular (pseudorotation)^{9,60} ligand exchange or to hindered rotation.^{9,61}

4.6 Six-Coordinate Phosphorus

The chemical shifts of six-coordinate phosphorus are found between –57 and –441 with most of the shifts between –80 and –290.⁶ The major factors determining the chemical shifts are electronegativity and anisotropic effects of the substituents. Increasing the overall charge of the species from +1 through zero to –1 shifts $\delta^{31}\text{P}$ to lower frequency, while incorporation of the phosphorus in a five-membered ring results in a shift of $\delta^{31}\text{P}$ in the opposite direction.^{6,9}

5 COUPLING CONSTANTS

Scalar spin–spin couplings of phosphorus to almost all elements of the Periodic Table are known, and remarkably large coupling constants up to 17000 Hz (!) have been observed. Compilations of phosphorus–element coupling constants can be found in several books.^{7–10,62} Representative values are contained in most of the compilations of ^{31}P chemical shift data.^{4–6,51–53} Specialized reviews on phosphorus–phosphorus,⁶³ phosphorus–hydrogen,⁶⁴ and phosphorus–carbon^{65,66} coupling constants are available.

Table 2 Observed Phosphorus–Phosphorus Coupling Constants

Coupling constant	<i>J</i> (Hz)	References
$^1J(\text{P}^{\text{III}}, \text{P}^{\text{III}})$	–55 to –670	8–10, 51–53, 63
$^1J(\text{P}^{\text{III}}, \text{P}^{\text{V}})$	–157 to –684	8–10, 63
$^1J(\text{P}^{\text{V}}, \text{P}^{\text{V}})$	–67 to +766	8–10, 63
$^2J(\text{P}^{\text{III}}, \text{P}^{\text{III}})$	–35 to +665	8–10, 63
$^2J(\text{P}^{\text{III}}, \text{P}^{\text{V}})$	–28 to +150	8–10, 63
$^2J(\text{P}^{\text{V}}, \text{P}^{\text{V}})$	11 to 210	8–10, 63
$^3J(\text{P}, \text{P})$	0 to 227	8–10, 63
$^4J(\text{P}, \text{P})$	2 to 35	9, 10, 63
$^5J(\text{P}, \text{P})$	5 to 9	67
$^6J(\text{P}, \text{P})$	3 to 12	67, 68
$^7J(\text{P}, \text{P})$	1 to 8	67
$^8J(\text{P}, \text{P})$	1 to 2	67
$^9J(\text{P}, \text{P})$	4	67

More information on specific phosphorus–element coupling constants can be found in the references in Tables 2 and 3.

It is generally observed, that the values of the reduced coupling constants $^nK(\text{P}, \text{X})$ decrease in the order $^1K(\text{P}, \text{X}) \gg ^3K(\text{P}, \text{X}) > ^2K(\text{P}, \text{X}) > ^4K(\text{P}, \text{X})$.⁹ In many cases, however, the order of $^3K(\text{P}, \text{X})$ and $^2K(\text{P}, \text{X})$ is reversed, due to structural factors. Coupling constants over more than four bonds are normally two or more orders of magnitude smaller than $^1K(\text{P}, \text{X})$. In special cases and particularly in compounds with a delocalized π system long-range coupling constants $^nJ(\text{P}, \text{P})$ for $n = 5$ – 9 ^{67, 68} and $^nJ(^{31}\text{P}, ^{13}\text{C})$ up to $n = 7$ ⁶⁹ have been observed.

The presence of a lone pair of electrons at the phosphorus atom or at the atom coupled with it seems to be associated with a negative one-bond reduced coupling constant $^1K(\text{P}, \text{X})$. An exception is provided by $^1K(^{31}\text{P}, ^1\text{H})$, however, which is positive. The magnitude of $^1K(\text{P}, \text{X})$ increases with increasing electronegativity of the substituents regardless of its sign. Linear relationships have been found between $^1K(\text{P}, \text{X})$ and the sum of the electronegativity of the substituents at the phosphorus atom for $^1K(^{183}\text{W}, ^{31}\text{P})$, $^1K(^{77}\text{Se}, ^{31}\text{P})$, $^1K(^{95}\text{Mo}, ^{31}\text{P})$, $^1K(^{31}\text{P}, ^{31}\text{P})$, $^1K(^{31}\text{P}, ^{13}\text{C})$, and $^1K(^{31}\text{P}, ^1\text{H})$.^{9, 10, 70}

In molecules with a trigonal bipyramidal geometry $^1K(\text{P}, \text{X})$ through the shorter equatorial bond is larger than through the longer axial bond.^{9, 10, 71} In transition metal–phosphine complexes the one-bond phosphorus–metal coupling constant is found to increase with decreasing *trans*-effect of the ligand in the *trans*-position to the phosphorus atom in the order $\text{MePh}_2\text{Si} > \text{Ph} > \text{Me} \gg \text{R}_3\text{P} > (\text{PhO})_3\text{P}$, $\text{CN} > \text{Et}_3\text{As} > \text{NO}_2 > \text{amine}$, NCO , $\text{NCS} > \text{Cl}$, Br , $\text{I} > \text{ONO}_2 > \text{F}$.^{9, 10} A bond angle and dihedral angle dependence of $^1K(\text{P}, \text{X})$ has also been discussed.^{5, 9, 72, 73}

Geminal coupling constants $^2K(\text{P}, \text{X})$ show, in principle, the same dependences as $^1K(\text{P}, \text{X})$; the signs are often reversed, however. For the three-coordinate trivalent phosphorus there is a dependence of $^2K(\text{P}, \text{X})$ on the dihedral angle between the phosphorus lone pair and the X nucleus,⁷³ which has been investigated for $^2J(^{31}\text{P}, ^{31}\text{P})$, $^2J(^{31}\text{P}, ^{13}\text{C})$, and $^2J(^{31}\text{P}, ^1\text{H})$. For tetracoordinate phosphorus a similar dependence is found with an electronegative substituent in place of the lone pair.⁹

Of general importance is the dependence of vicinal reduced coupling constants $^3K(\text{P}, \text{X})$ on the dihedral angle between the phosphorus and the X nucleus (Karplus relationship), which has been investigated for a number of compounds. In all

cases a minimum near 90° and maxima at 0° and 180° are observed.^{9, 10, 74}

5.1 Phosphorus–Phosphorus Coupling Constants

Typical ranges for P,P coupling constants are given in Table 2. The value of $^1J(^{31}\text{P}, ^{31}\text{P})$ is negative between trivalent phosphorus atoms and, where the sign is known, also between trivalent and pentavalent phosphorus atoms. Between pentavalent phosphorus atoms $^1J(^{31}\text{P}, ^{31}\text{P})$ is often positive. One-bond phosphorus–phosphorus coupling constants show a large stereochemical dependence on rotation about the P–P bond, especially when there are lone pairs at the phosphorus atoms.^{8–10}

Geminal P(III), P(III) coupling constants are mostly positive and extend up to +665 Hz. In acyclic compounds geminal P(III), P(V) couplings range mainly between +50 Hz and +150 Hz, whereas for cyclic compounds smaller and negative values are found. The value of $^2J(^{31}\text{P}, ^{31}\text{P})$ between pentavalent phosphorus atoms in acyclic compounds is generally small (11–43 Hz), but can assume large values up to +210 Hz in cyclic compounds.⁸

5.2 Phosphorus Couplings to Other Nuclei

Typical ranges for the coupling constants of phosphorus to other elements of the Periodic Table are given in Table 3. The signs of the coupling constants, where known, have also been included. The value of $^1J(^{31}\text{P}, ^1\text{H})$ tends to increase with increasing oxidation state and coordination number of phosphorus; the individual ranges overlap considerably, however.⁷⁰ One-bond phosphorus–fluorine coupling constants show the opposite trend, in accord with the opposite signs of $^1J(^{31}\text{P}, ^1\text{H})$ and $^1J(^{31}\text{P}, ^{19}\text{F})$.^{9, 10} An isotope effect of ^2H on $^1J(^{31}\text{P}, ^1\text{H})$ has been reported.¹⁰³ The $^1J(^{31}\text{P}, ^{15}\text{N})$ value is positive (+24 to +105 Hz) in trivalent, generally positive (–44 to +60 Hz) in tetravalent, and negative (–40 to –80 Hz) in pentavalent phosphorus compounds. The $^1J(^{77}\text{Se}, ^{31}\text{P})$ value is larger for a phosphorus–selenium double bond (–500 to –1200 Hz) than for a single bond (–100 to –500 Hz). Similarly $^1J(^{125}\text{Te}, ^{31}\text{P})$ is larger for $\text{P}=\text{Te}$ (1324–2290 Hz) than for $\text{P}-\text{Te}$ (80–996 Hz).^{8, 9} Exceptionally large values, reaching orders of magnitude of the corresponding one-bond coupling constants, are observed for $^2J(^{77}\text{Se}, ^{31}\text{P})$,⁹² $^2J(^{119}\text{Sn}, ^{31}\text{P})$,¹⁰ $^2J(^{205}\text{Tl}, ^{31}\text{P})$,¹⁰² and $^2J(^{207}\text{Pb}, ^{31}\text{P})$ ¹⁰⁴ in transition metal complexes.

6 APPLICATIONS OF ^{31}P NMR SPECTROSCOPY

Phosphorus-31 NMR spectroscopy has been used to monitor the progress of chemical reactions and exchange equilibria since its early days. Today ^{31}P NMR spectroscopy is a powerful diagnostic tool in practically all areas of preparative chemistry where phosphorus is present. Alone, or in combination with the NMR spectroscopy of other nuclei, it is mostly used for the identification and structure elucidation of phosphorus compounds. The enantiomeric purity of chiral alcohols, thiols (via the corresponding phosphites and thiophosphonates), and phosphines is conveniently checked by ^{31}P NMR. Based on

$^2J(^{109}\text{Ag},^{31}\text{P})$	9 to 10		8			

the pH dependence of $\delta^{31}\text{P}$, the $\text{p}K_{\text{a}}$ values of phosphoric acids have been determined. Phosphorus-31 NMR is also extensively used for the investigation of dynamic processes.^{9,10}

In biochemistry and medicine in vivo ^{31}P NMR and ^{31}P NMR imaging gain increasingly in importance.^{8,105,106} Oxygen-18 isotope effects on ^{31}P nuclear shielding are extensively used to study the chirality of phosphorus compounds and the stereospecificity of enzymatic reactions.⁴⁴

1 INTRODUCTION

Polymorphism is ubiquitous in solid state chemistry, commonly occurring for a very wide range of materials. Polymorphs are different solid forms (usually crystalline) of a given compound. The differences lie in solid state structure, i.e. in the spatial arrangement of the atoms or molecules. They may be relatively minor (e.g. variations in mutual orientations of molecules) or major (leading, for instance, to substantially different atomic arrangements). Sometimes other terms are used for the phenomenon. Thus, when concerning different forms of the elements, the word allotrope is used, instead of polymorph. Also, polymorphs which have structures differing in the stacking sequence of layers (for example, in silicon carbide) are called polytypes.

A somewhat similar phenomenon is the ability of many compounds to incorporate solvent molecules in their structure during crystallization from solution. Thus compounds frequently exist in both anhydrous and hydrated forms, the crystal structures of which may be essentially identical or profoundly different. Other solvent molecules, such as acetone and chloroform, may be similarly incorporated. Ultimately this relates to the existence of clathrates, for which the structure may only be stable when both host and guest molecules are present. Sometimes hydrates lose water readily; on other occasions anhydrous forms may be hygroscopic. Although this article will concentrate on true polymorphism, the 'pseudopolymorphism' of solvates, which can carry similar NMR connotations, will be mentioned at times.

Of course, another closely-related topic is that of phase changes and phase diagrams, together with similar matters concerning the formation and interchange of polymorphic forms. These questions will be largely ignored in the present article. Under given conditions of temperature, pressure, etc., only one polymorph will clearly be favored by thermodynamic considerations. Frequently, however, kinetics of interconversions will be slow, and several forms will exist at ambient temperature and pressure for times in excess of the minimum required to obtain NMR spectra. Such metastable forms may be obtained, for instance, by crystallization from a solvent or by quenching from a temperature at which they are stable. The present article will concentrate on NMR data obtained under standard

working conditions (atmospheric pressure and ambient temperature).

Cases of polymorphism and related phenomena may be divided into those involving molecular crystals and those relating to macromolecular structures (in one, two, or three dimensions). Of course, the bonding in the latter implies that interconversion between forms (e.g. between graphite and diamond) is extremely difficult. Indeed, it might be argued that cases of macromolecular structural differences, which require bond-breaking for interconversion (as for silicon carbide) are not properly labeled as polymorphic since they are more analogous to some types of isomerism in organic compounds. However, although interconversions between molecular polymorphs are usually relatively easy, it must not be assumed that intermolecular forces are negligible. Frequently they involve hydrogen bonding, with substantial energies.

Polymorphism is particularly important, and has been extensively investigated by NMR, for pharmaceutical compounds, for silicates and zeolites, for polymers (including naturally occurring materials such as cellulose and chitosan, as well as synthetic polymers), and for ceramic materials.

2 APPLICABILITY OF NMR

Since the electronic environments of corresponding atoms in different polymorphs of the same compound differ, the NMR chemical shifts will be in principle distinguishable. Indeed, the total NMR spectrum can clearly act as a fingerprint to identify polymorphic forms. Such differences are expected to be similar in magnitude to the crystallographic splittings observed when molecules or atomic groupings of the same chemical type are in locations in the unit cell unrelated by symmetry. The 'fingerprint' is of the crystallographic asymmetric unit, and simply counting the number of resonances may, on occasion, suffice to distinguish between polymorphs.

The techniques most commonly used to distinguish polymorphs are DSC, IR, and powder XRD, but all three have disadvantages. The DSC method is very crude, since it gives little or no chemical information. IR spectroscopy often suffers from lack of resolution and from difficulties in interpreting intensities. Powder XRD is often the preferred technique, but it is not sensitive to poorly crystalline or amorphous forms. NMR does not suffer from any of these problems, and the only drawback is the cost of the equipment.

Polymorphs often differ in molecular-level mobility, and hence in NMR relaxation times, but these are unlikely to be used as distinguishing features, except perhaps for polymeric systems.

3 MOLECULAR POLYMORPHS

The principal area of investigation of molecular polymorphism is that of pharmaceutical compounds. This is for very practical reasons: polymorphs sometimes show differing physiological activity (largely as a result of differences in rates of dissolution) and government regulations therefore require pharmaceutical companies to identify carefully the polymorphic form of their products. Moreover, very small changes in

conditions of preparation can readily result in a difference in polymorphic form, and scale-up can reveal problems not found in laboratory synthesis, so that an understanding of polymorphic variations is very important in pharmaceutical chemistry.

The first application of ^{13}C CP MAS NMR to pharmaceutical polymorphism appears to be that reported by Balimann et al.¹ in 1981, which featured spectra of two forms of Nolvadex (the ICI trade name for the generic tamoxifen). In the late 1980s and early 1990s the groups of Byrn^{2,3} and of Harris⁴⁻⁶ were particularly active in this area.

Steroids appear to be particularly prone to give rise to polymorphic forms. Cortisone acetate (**1**) is a typical example. A substantial number of polymorphs and solvated forms are known, and seven have been studied⁴ by MAS NMR. Three of the polymorphs are anhydrous, and Figure 1 illustrates the ^{13}C CP MAS spectra for the high-frequency region (containing resonances from C-3, C-5, C-11, C-20 and C-22).

Immediately, two important conclusions can be made:

1. NMR readily distinguishes the three anhydrous forms (as it does the five hydrates and other solvates).
2. Whereas Forms I and II have asymmetric units consisting of a single molecule (since only five signals are seen in this region), Form III is more complex. In fact, expanded-scale spectra for all the carbon resonances show that Form III has three molecules in the asymmetric unit.

One can go further when peak assignments are firmly established. The apparent variation in the relative intensities of the two peaks on the right in Figure 1(a) and (b) arises from differing spinning sideband intensities. Complete analysis of the spinning sideband manifolds (at low spin rates) shows that C-5 and C-22 have distinguishable shielding anisotropies and asymmetries, which in turn indicates that the order of their isotropic chemical shifts is interchanged between Forms I and II. This variation can be correlated with hydrogen

Figure 1 Carbon-13 CP MAS NMR spectra⁴ (high-frequency region only) of three polymorphs of cortisone acetate (**1**) at 50.3 MHz

Table 1 Isotropic Chemical Shifts^a for C-3, C-5, and C-22 of the Anhydrous Polymorphs of Cortisone Acetate

Carbon	Form I	Form II	Form III
C-3	202.8 ^b	198.9	203.0 ^c , 203.0 ^c , 198.2
C-5	175.7	171.0	173.7, 173.7, 166.9
C-22	169.8	175.2 ^b	174.3 ^c , 171.5, 170.3

^aGiven as δ_{C} (ppm).

^bShown by X-ray crystallography to be the acceptor site for hydrogen bonding.

^cConcluded from the NMR evidence to be the acceptor site for hydrogen bonding.

bonding,^{2,4} which causes an increase in chemical shift of 3–4 ppm at the acceptor carbonyl carbon resonance. Table 1 shows the assignments for carbons C-3, C-5 and C-22 for the three anhydrous forms, and indicates the known acceptor positions for hydrogen bonding. One can conclude that, of the three molecules in the asymmetric unit of Form III, two are hydrogen bonded at C-3 and the third, in contrast, at C-22. It may be noted that conjugation appears to relay the effect of hydrogen bonding on the chemical shift from C-3 to C-5.

This example illustrates how polymorphic form can affect chemical shifts. Unfortunately, matters are not often so simple. The differences in chemical shifts between analogous carbons for different polymorphs may arise either from *intermolecular* effects (packing, direct influence of neighboring molecules, hydrogen bonding, etc.) or *intramolecular* effects (variations in geometry and/or conformation). There is rarely any way that NMR can distinguish between the two influences. Of course, if crystal structures are known from X-ray studies, then knowledge of influences on chemical shifts obtained from solution state studies or by theory can be brought to bear. A case where intramolecular differences (but correlated with intermolecular differences!) are thought to be important is that of 4'-methyl-2'-nitroacetanilide (**2**), which exists in two forms (white and yellow), both of which have been subjected to study by single-crystal X-ray diffraction. In the white form, both the amide and nitro groups are in planes at a substantial angle (ca. 44°) to the plane of the aromatic ring, giving restricted conjugation and preventing intramolecular hydrogen bonding. On the other hand, the yellow form (with two molecules in the asymmetric unit) has more nearly coplanar groups (dihedral angles between 12° and 31°), allowing intramolecular hydrogen bonding between the amide NH and one of the nitro group oxygens. These facts suffice to explain the differences in chemical shifts between the polymorphs.⁵ For example, the white form (C–NO₂ dihedral angle, 44.0°) has $\delta(\text{C-2}) = 144.1$ ppm whereas the yellow form (C–NO₂ dihedral angles, 18.0° and 12.3°) gives $\delta(\text{C-2}) = 135.9$ and 133.0 ppm (presumably respectively).

Certain simple but important measurements can be made of polymorphism via the fingerprinting ability. For example:

1. Mixtures of polymorphs can be readily studied and minor components can be quantified,⁴ in favorable cases down to the 1% level.
2. NMR spectra can be used to monitor the polymorphic variations produced by different formation conditions (e.g. different rates of crystallization produced by cooling a solution quickly or slowly).⁴
3. Polymorphism can be studied directly in pharmaceutical tablets. Saindon et al.³ have pointed out that the CP MAS technique can be used to discriminate against signals deriving from the excipient.

The combination of single-crystal XRD and CP MAS NMR for the study of polymorphism is particularly powerful. The former can give precise atomic positions but is frequently feasible for only some of the forms of a product (because of difficulties in growing suitable crystals). NMR, however, can almost always be relied upon to yield spectra of all polymorphs available in sufficient quantity, and interpretation is greatly aided by X-ray information on any one form. For example, of the two forms of fosinopril sodium, one was examined using single-crystal X-ray diffraction techniques, then both were studied⁷ by CP MAS NMR of ¹³C. The results provided by NMR enabled the conclusion to be drawn that the environment of the acetal side chain of fosinopril sodium differed in the two polymorphs. In this case ³¹P CP MAS NMR was also used, and showed a significant chemical shift difference (2.2 ppm) between the forms.

It is possible to detect conformational disorder within polymorphs by CP MAS NMR. Thus Stoltz et al.⁸ have shown that peak intensities for the monohydrate of oxyphenbutazone give a site ratio consistent with X-ray results in terms of sterically-favored isomers. However, it must be said that since CP MAS NMR spectra are obtained on microcrystalline or powdered material, it is not easy to differentiate between mixed crystals and disorder in a single type of crystal.

Differences in bonding between polymorphs can sometimes be quite startling but readily detectable by NMR. Thus, for 2-aminobenzoic acid (**3**), ¹³C MAS NMR reveals⁹ that Form I gives two signals each for C-1 and C-2. These are at chemical shifts which are characteristic of the normal and zwitterionic structures (**3**)A and (**3**)B, respectively, indicating that the unit cell contains equal proportions of each form. On the other hand, Forms II and III give spectra showing that each has an asymmetric unit containing one molecule of structure (**3**)A only.

Interestingly, the ¹³C spectra of Forms II and III are so similar as to be virtually indistinguishable. In these cases, it is necessary to turn to nuclei other than ¹³C to differentiate. The proton CRAMP spectra of the two forms are, in fact, very different (Figure 2). Form II of the compound gives a

Figure 2 Proton CRAMP spectra⁹ of two polymorphs of 2-aminobenzoic acid (**3**) at 200.13 MHz. The sample of Form III contains a small amount of Form II, which gives rise to the hydrogen-bonded peak at δ 12.3 ppm. The peak at $\delta \sim 1.5$ ppm in each spectrum is due to an impurity in the Kel-F rotors used. The broad line (assigned to NH_2 and CO_2H protons) underlying the spectrum of Form III is clearly visible

strong signal at $\delta_{\text{H}} = 12.3$ ppm, indicative of a hydrogen-bonded CO_2H group (in agreement with single-crystal X-ray results). This is not present for Form III (the crystal structure of which is unknown)—from which it can be deduced that hydrogen bonding is probably absent. However, the situation is complicated by the fact that there are proton-exchange processes occurring, involving amino and (in some cases) carboxylic acid protons, at a rate comparable with the NMR timescale, producing broad bands underlying the sharper aromatic proton signals at ambient probe temperature.

4 POLYMORPHISM AND MOLECULAR MOBILITY

In addition to the effects on chemical shifts arising from differences in intermolecular environment and intramolecular geometry between molecules of different polymorphs, variations in molecular level motion can often also be detected. A case in point is illustrated in Figure 3, which shows ambient probe temperature ¹³C CP MAS spectra¹⁰ of two forms

Figure 3 Carbon-13 CP MAS spectra¹⁰ of two forms of bisphenol-A diacetate (**4**) at 50.3 MHz and ambient probe temperature. Signals not indicated by numbers in (a) [and corresponding peaks in (b)] are spinning sidebands

of bisphenol-A diacetate (**4**). Clearly, Form I gives a much more complex spectrum than Form II, as is consistent with the single-crystal X-ray results, which show that in the former case the asymmetric unit consists of two entire molecules. The second feature of importance is the breadth of the resonances for the aromatic CH carbons (C-4, C-5, C-7 and C-8) for Form II, which suggests there is substantial averaging, probably arising from 180° ring-flips of the phenylene rings (possibly by simultaneous motion of the two halves of the molecule). This suggestion is readily confirmed by variation of the temperature.

Such variable temperature ¹³C CP MAS NMR experiments have been used¹¹ to study the motion of a phenylene ring about the *para* axis of one form of sulfanilamide, (**5**). Just below room temperature the C-3/C-5 resonance (but not the C-2/C-6 signal) is observably split because the SO₂NH₂ substituent

is twisted with respect to the ring. An Arrhenius activation energy, E_a , of $63 \pm 4 \text{ kJ mol}^{-1}$ for the (assumed) 180° ring-flip was obtained. It should be noted that rapid motion of this type would not be detected by XRD.

An example from an entirely different area of chemistry concerns the polymorphism of phosphorus pentachloride, PCl₅. The stable form (Phase II) of this compound under normal conditions is ionic, with the structure PCl₄⁺ PCl₆⁻. Both ions are very mobile at ambient temperature, so that shielding anisotropy at the phosphorus nuclei is eliminated and the chlorine nuclei relax very rapidly. The latter effect causes self-decoupling of the chlorines and the net effect is that ³¹P MAS spectra consist¹² of two sharp lines, one for each anion. However, Phase III, which can also be studied at ambient probe temperature, has the stoichiometry [PCl₄]₂⁺[PCl₆]₂⁻Cl⁻. Since this form, like Phase II, contains PCl₄⁺ and PCl₆⁻ ions, the ³¹P MAS spectrum also consists of two bands, but at 81 MHz the resonances are broad and splittings arising from (Cl,P) coupling are seen at 36 MHz. Thus self-decoupling is substantially less efficient for Phase III than for Phase II, probably indicating more restricted rotational mobility for the ions in the former.

5 MACROMOLECULAR POLYMORPHS

Two types of example from widely different chemical areas should suffice to show some of the general features of polymorphism in macromolecular systems. Silicon carbide exemplifies the situation where the structure is three-dimensional so that interchange between forms is not feasible. The different polymorphs are essentially frozen-in at the time of preparation. All structures have alternating Si and C atoms, with all coordinations tetrahedral (though mostly not with the full symmetry). The structural differences between some of the forms can be appreciated from Figure 4, which shows a plane including the *c* crystallographic axis and alternating Si and C atoms in that plane for four forms of the material. It is evident that the detailed environments of all silicon atoms of the 2H form are equivalent, as is also the case for the β form (though β and 2H environments are not identical). However, the 4H form contains two types of Si and the 6H three types. The ²⁹Si spectra (Figure 5) show¹³ the expected number of signals for the four forms. Similar considerations apply to the ¹³C spectra. There is also a range of other forms. Assignment of the signals for the 4H and 6H polymorphs is not easy but has been made.^{13,14} The separate signals have different relaxation times, probably as a result of the presence of impurities. Silicon carbide is a case where the amorphous material can also exist, without sizable domains of any of the potentially ordered structures. Such material gives rise to broad ²⁹Si and ¹³C resonances, usually characterized by shorter values of *T*₁ than the crystalline material, probably because impurities tend to concentrate in amorphous regions.

Of course, silica provides the outstanding example of a compound with multiple polymorphs. Not only are there well-characterized crystalline forms (quartz, cristobalite, tridymite, etc.), together with the common amorphous glass, but it seems that many types of zeolites can be obtained with all aluminum atoms replaced by silicon so that they become silica polymorphs. Since zeolites are treated in other entries in this Encyclopedia they will not be discussed here. The book

Figure 4 Schematic structures for silicon carbide polymorphs. The vertical arrows represent repeat distances

by Engelhardt and Michel¹⁵ contains a useful discussion of NMR studies of nonzeolitic silica polymorphs (pp. 170–175). The ^{29}Si chemical shifts cover a wide range ($\delta_{\text{Si}} \sim -107$ to -121 ppm), the variation being attributed to differences in mean SiOSi bond angles, α , an increase in shielding resulting from widening SiOSi angles. A number of specific relationships have been proposed,¹⁶ including (from theoretical considerations) $\delta_{\text{Si}} = -247.05\rho + 2.19$, where $\rho = \cos \alpha / (\cos \alpha - 1)$. Of course, many of the silica polymorphs differ in the number of different crystallographic sites. Coesite, for instance, gives two widely-spaced ^{29}Si signals ($\delta_{\text{Si}} = 108.1$ and

113.9 ppm), in accord with its structure.¹⁶ In contrast to all the four-coordinate silica polymorphs, stishovite, which contains six-coordinate silicon, gives a signal at $\delta_{\text{Si}} = -191$ ppm.¹⁶ As with silicon carbide, amorphous forms of silica (glass!) are well known.

Organic polymers may also show polymorphism. One of the early examples of CP MAS NMR related to the case of isotactic polypropene, which exists in several crystalline forms usually as domains separated by amorphous material. In effect, the chains constitute infinite one-dimensional bonded structures with weaker forces between the chains. The systems therefore are intermediate between the molecular polymorphs discussed in Section 3 and the infinite three-dimensional structures of SiC and SiO₂. The structure of the α form of polypropene is shown in Figure 6(a). The helical polymer units occur as pairs of interlocking chains with opposing handedness. This creates a situation where there are two distinct methyl sites, with two-thirds of the groups in a given helix facing the companion helix, and the remaining third facing outwards. Thus a 2:1 doublet is expected for the methyl carbons, and this is observed¹⁷ in practice. A similar situation obtains for the CH carbons.

In contrast, the crystal structure of the β form contains separate groups of helices of the two types of handedness, with no pairing [Figure 6(b)]. The NMR spectrum therefore lacks the well-defined splitting shown by that of the α form.

Figure 6 Diagrammatic crystal structures for two forms of isotactic polypropene: (a) α form; (b) β form. The figures show projections of the chains perpendicular to their axes, with the corners of the triangles indicating the positions of methyl groups. The arrows represent the handedness of the helices

Of course, isotactic polypropene also contains a significant proportion of amorphous material which, as usual, gives rise to somewhat broadened CP MAS ^{13}C lines. The differences between the α and β forms of isotactic polypropene arise from intermolecular packing of the polymer chains. Far greater differences occur, as expected, in NMR spectra^{17,18} for polymer forms differing in tacticity (such as isotactic and syndiotactic polypropene). However, differences in tacticity are not normally classed under polymorphism.

Biochemical polymers such as cellulose and chitosan also give rise to polymorphism, which has been studied by solid state NMR methods.^{19,20}

1 INTRODUCTION

Nuclei with spin quantum number $I \geq 1$ have an electric quadrupole moment that couples with the inhomogeneous internal electric fields existing in molecules and solids. Since this quadrupolar interaction is usually stronger than other interactions such as chemical shift and dipole–dipole couplings, it dominates the NMR spectra of quadrupolar nuclei in solid materials. Liquid state NMR spectra of quadrupolar nuclei are not affected to a comparable extent, because the fast isotropic tumbling of the molecules greatly diminishes the impact of the quadrupolar interaction. While the NMR signals of quadrupolar nuclei in solids are split into multiplets that at times broaden the lineshapes of powder samples over many megahertz, the quadrupolar interaction does not split the NMR lines of liquid samples. Instead, it has a pronounced effect on the T_1 and T_2 relaxation times of nuclei in liquids (see *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration* and *Relaxation Theory for Quadrupolar Nuclei*). The NMR spectra of quadrupolar nuclei in liquid crystals, where the quadrupolar splitting is partially reduced, provide a wealth of information concerning molecular orientation and dynamics (see *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods* and *Liquid Crystalline Samples: Deuterium NMR*).

This article is devoted to the solid state aspects of the quadrupolar interaction. Since many subtopics from this area of NMR are discussed elsewhere in the Encyclopedia, the aim of this article is to provide a general overview rather than comprehensive discussions of each specific method. The first two sections following this introduction summarize the quantum mechanical properties of quadrupolar spins and their response to radiofrequency pulses. This survey is given without theoretical derivations and with only a few mathematical formulas. The important experimental approaches are catalogued in Section 4. Some of the fundamental theoretical concepts underlying quadrupolar spin properties are presented in Section 5.

Quadrupolar effects in NMR of solids were first reported and analyzed in 1950 by Pound.¹ Introductions to NMR of quadrupolar nuclei are provided in the classic 1957 review article by Cohen and Reif² and in the textbooks by Abragam³ and Slichter.⁴ Kanert and Mehning also covered the basics of

quadrupole NMR in their 1971 review of quadrupole NMR of disordered cubic solids.⁵ Nuclei with half-integer spins have distinctive quantum mechanical properties that have led to the development of special methods for their detection. Progress in this area was summarized in a 1993 review article by Freude and Haase.⁶ NMR of integer spin nuclei is almost exclusively limited to ^2H and ^{14}N . Although both are $I = 1$ spins, the disparate orders of magnitude of their quadrupolar interaction energies necessitate different methodologies for their study in the solid state. Deuterium NMR spectroscopy was reviewed by Spiess⁷ in 1985.

2 BASIC SPIN PROPERTIES

2.1 Nuclear Electric Quadrupolar Interaction

The nuclear quadrupolar interaction is the coupling of the electric quadrupole of the nucleus with the gradient of the electric field generated by the other charges in the system. The quadrupole moment is usually denoted by eQ and the magnitude of the electric field gradient (EFG) by eq , where e is the elementary charge. Since it is impractical to produce NMR-detectable EFGs by means of external charged conductors, the gradients are exclusively generated by the electrons and nuclei of molecules and crystals. Thus, the size of the quadrupolar interaction experienced by a particular nucleus is a constant that is characteristic of the molecular or crystalline environment. Its value in frequency units, e^2qQ/h , is called the nuclear quadrupolar coupling constant (NQCC). In this Encyclopedia, we use the letter χ as shorthand notation for e^2qQ/h . A variety of different symbols (C_q , C_Q , C_{qcc} , $\mathcal{N}_{zz}$, ...) are found in other publications (see also *Quadrupolar Interactions*).

Closely related to the NQCC is the so-called quadrupolar frequency ν_Q (in Hz) or ω_Q (in rad s^{-1}), in this article defined as

$$\nu_Q = \frac{\omega_Q}{2\pi} = \frac{3\chi}{2I(2I-1)} \quad (1)$$

The use of ν_Q is often preferred over that of χ , because it simplifies equations. Moreover, the quadrupolar frequency describes the actual strength of the quadrupolar interaction more closely than does the NQCC. It should be noted that equation (1) is not a universally accepted definition of ν_Q , although in literature dealing with half-integer spins it is often (but not always) found in this form. However, in the case of $I = 1$ authors usually prefer $\nu_Q = \frac{3}{4}\chi$ over the $\nu_Q = \frac{3}{2}\chi$ that follows from equation (1). For the sake of uniformity, we shall adhere to equation (1) for all values of I throughout this article.

The EFG is a three-dimensional entity with the properties of a tensor. To describe it fully, we need to specify its size, shape, and orientation. The quantity eq was introduced above as a parameter of the size. The shape is characterized by the asymmetry parameter η , which is a measure of the deviation of the EFG from axial symmetry. η can have any value between 0 and 1, with $\eta = 0$ corresponding to axial symmetry. The orientation of the EFG with respect to the molecular or crystalline structure is defined by three Euler angles. The

tensor properties are more fully defined in Section 5.1. In the literature, quadrupolar interactions are commonly reported by specification of their NQCC and η . The angular parameters are not usually provided unless orientational information is of special interest.

The quadrupolar interaction vanishes in three general cases.

1. No quadrupolar interaction is ever associated with an $I = \frac{1}{2}$ nucleus, because eQ vanishes for all subatomic particles with spin quantum number $I = 0$ or $\frac{1}{2}$.
2. The NQCC is zero when a quadrupolar nucleus is positioned at a cubic (octahedral or tetrahedral) site, because then $eq = 0$ by symmetry.
3. The quadrupolar interaction of a nucleus belonging to a molecule in an isotropic liquid or a gas is averaged to zero by the rapid tumbling motion of the molecule.

2.2 NQR and NMR Spectra of Quadrupolar Nuclei

The nature of magnetic resonance spectra of quadrupolar nuclei in solids depends to a large extent on the size of the electric quadrupolar interaction relative to that of the Zeeman interaction with the externally applied magnetic field B_0 . The strength of this magnetic interaction is given by the Larmor frequency $\omega_0 = 2\pi\nu_0 = \gamma B_0$, where γ is the gyromagnetic ratio. In this subsection, we review the general features of magnetic resonance spectra for the various magnitude ranges of the ratio ν_0/ν_Q .

We begin with the case where no magnetic field is applied at all ($\nu_0 = 0$). The quadrupolar interaction then splits the magnetic energy levels of the nuclear spins into patterns like those shown in Figure 1. The energy levels are associated with particular orientations of the nuclear spin axis with respect to the EFG axes, and can thus be identified by magnetic quantum numbers m . The spectroscopic transitions among these magnetic states can be detected with the regular radiofrequency methods of magnetic resonance. This branch of spectroscopy is known as nuclear quadrupole resonance (NQR). Its first spectrum was observed by Dehmelt and Krüger in 1949.⁸ Unlike the extremely broad high-field NMR spectra of quadrupolar nuclei in randomly oriented powder samples

(see below), the NQR resonances are sharp. In fact, they provide the most precise measurements of the quadrupolar frequency and the NQCC. Although NQR employs the radiofrequency methods of magnetic resonance, it is not an NMR technique in the proper sense, since NMR is defined as a spectroscopy associated with a Zeeman field. NQR is therefore outside the scope of this Encyclopedia, although some aspects of it are discussed in the articles on *SQUIDS* and *Zero Field NMR*. For further literature on the subject, the reader is referred to the classic monograph by Das and Hahn,⁹ several other books and tabulations,^{10–12} and the review articles in the series ‘Advances in Nuclear Quadrupole Resonance’.¹³

A weak magnetic field, corresponding to a Larmor frequency ν_0 smaller than ν_Q , shifts and splits the NQR lines. The frequency shifts of this so-called Zeeman effect of NQR are functions of the orientation of the magnetic field with respect to the crystal axes. Consequently, in randomly oriented powder samples, the effect is observed as a broadening of the peaks.

When ν_0 is much larger than ν_Q , we are in the regime of NMR. In the extreme limit of vanishing ν_Q , the energy levels are the $2I + 1$ Zeeman levels, $E_m = m\omega_0$, giving rise to $2I$ coinciding transitions of frequency ν_0 . A relatively small quadrupolar interaction, $\nu_Q \ll \nu_0$, shifts the eigenvalues of the Zeeman levels and splits the NMR spectrum into $2I$ peaks. Examples for spins $I = 1$ and $\frac{5}{2}$ are shown schematically in Figure 2. For the theoretical description of these effects, we follow the methods of perturbation theory and express the quadrupolar corrections to the energy levels as the sums of first-order terms of order ω_Q and second-order terms of order ω_Q^2/ω_0 (see Section 5.3). Third- and higher-order terms do not need to be considered.

The main features of quadrupolar NMR spectra are governed by the equation describing the orientation dependence of the first-order energy corrections $\Delta E_m^{(1)}$ of the Zeeman levels m :

$$\Delta E_m^{(1)} = \frac{1}{2}\Delta\omega_Q(\theta, \phi)[m^2 - \frac{1}{3}I(I+1)] \quad (2)$$

where $\Delta\omega_Q$ is a fraction of ω_Q and is a function of the polar angles θ and ϕ which relate the Zeeman field direction to the EFG principal axes system (see Section 5.1 and Figure 11):

$$\begin{aligned} \Delta\omega_Q(\theta, \phi) &= 2\pi\Delta\nu_Q(\theta, \phi) \\ &= \frac{1}{2}\omega_Q[3\cos^2\theta - 1 - \eta\sin^2\theta\cos 2\phi] \end{aligned} \quad (3)$$

$\Delta\nu_Q$ (or $\Delta\omega_Q$) is called the quadrupolar splitting because the $2I$ lines in the spectrum are, to first order, equally spaced by $\Delta\nu_Q$. This follows from equation (2), which predicts that the first-order frequency shifts $\Delta\nu_{m \leftrightarrow m+1}^{(1)}$ of the allowed transitions $m \leftrightarrow m+1$ are given by

$$\Delta\nu_{m \leftrightarrow m+1}^{(1)} = \Delta\nu_Q(\theta, \phi)(m + \frac{1}{2}) \quad (4)$$

In powder samples, the orientation dependence of $\Delta\nu_Q$ broadens the individual transitions and causes them to overlap. However, the $-\frac{1}{2} \leftrightarrow \frac{1}{2}$ transition of noninteger spins ($I = \frac{3}{2}, \frac{5}{2}, \frac{7}{2}, \frac{9}{2}$) does not experience a first-order broadening [$m = -\frac{1}{2}$ in equation (4)]. Consequently, this ‘central transition’ stands out as a relatively sharp peak at the center of the ‘satellite transitions’. It is clear from equation (4) that there

Figure 1 Quadrupolar energy levels in zero magnetic field. These two examples are for axial symmetry of the EFG. If the EFG is not axially symmetric, the transition frequencies are more complicated functions of the quadrupolar frequency ν_Q and the asymmetry parameter η , while the eigenstates are linear combinations of m states. Furthermore, the $m = \pm 1$ degeneracy of the $I = 1$ states is lifted when $\eta \neq 0$. However, the eigenstates of half-integer spins remain degenerate in pairs for any value of η .

Figure 2 (a) Energy levels of spins $I = 1$ and $\frac{5}{2}$ in a Zeeman field, in the absence and in the presence of a quadrupolar interaction. The frequencies of the allowed ($\Delta m = 1$) transitions are indicated with first-order quadrupolar corrections. The arrows mark forbidden ($\Delta m = 2, 3$) transitions. (b) The corresponding quadrupole-split NMR spectra. $\omega_0 = 2\pi \nu_0$ is the Larmor frequency and $\Delta \omega_Q = 2\pi \Delta \nu_Q$ is the quadrupolar splitting

is no central transition associated with integer-spin nuclei. The dependence of $\Delta \nu_Q(\theta, \phi)$ on the orientation is similar to that of the anisotropic chemical shift. However, unlike the chemical shift, the first-order quadrupolar effect has no isotropic contribution, implying that the centers of gravity of the spectral distributions are not shifted. Thus, each satellite transition has a powder lineshape characteristic of the value of η , and is centered around the Larmor frequency. Figure 3 shows a few simulated examples for $I = 1$ and $\frac{5}{2}$.

The broadening of the satellites is often too large to be captured within the bandwidth of the NMR spectrometer. In such a case, we only observe the central transition, the lineshape of which is dominated by second-order quadrupolar shifts. The orientation dependence of this shift is of a different nature to that of the first-order satellite shift. A consequence of this is that it contributes to an isotropic shift of the order of ν_Q^2/ν_0 (see equation (15) in Section 4.3).

Equation (2) shows further that levels m and $-m$ have identical first-order energy shifts. Therefore, in addition to the central transition, there are forbidden transitions $\Delta m = 2, 3, \dots$ (indicated in Figure 2 by arrows) with transition frequencies that are not affected to first order by the quadrupolar interaction. The experimental methods of double

quantum excitation and overtone spectroscopy of $I = 1$ nuclei take advantage of this special property (see Section 4).

The energy-level diagrams of Figure 4 illustrate the transition from the NQR limit to the NMR limit. The figure shows the variation of the energy levels of a spin- $\frac{3}{2}$ when the ratio ν_0/ν_Q changes gradually from 0 to ∞ . This is shown for two cases, both with an axially symmetric EFG—one with the EFG symmetry axis $\mathbf{q}$ parallel to the field $\mathbf{B}_0$, and one with $\mathbf{q}$ perpendicular to $\mathbf{B}_0$. The difference between the two sets of energy curves demonstrates the strong dependence of the transition frequencies on the relative orientations of the EFG and $\mathbf{B}_0$. When ν_0 is of the order of ν_Q , the powder spectra are sufficiently broad, that detection of magnetic resonance becomes impractical within the limitations of bandwidth and sensitivity of equipment currently in use.

Figure 4 also indicates the spin states in the limiting cases. Note that these eigenstates are quantized along the symmetry direction of the prevailing field, as is indicated by the Q and Z subscripts on the quantum numbers m . In general, these states are not identical. In fact, they are linear combinations of each other. A certain amount of mixing of the pure Zeeman states occurs even when the quadrupolar interaction is small in comparison with the Zeeman interaction. We say that the spins are then ‘no longer quantized along the Zeeman direction’

Figure 3 First-order quadrupolar spectra of powder samples simulated for $I = 1$ and $\frac{5}{2}$ and for three values of the asymmetry parameter η . The lineshapes of individual transitions are drawn below the spectra. The central transition peaks of $I = \frac{5}{2}$ are off scale. The frequency scale is in units of the quadrupolar frequency ν_Q as defined in equation (1). The Larmor frequency is at the center of the spectra

(see Section 5.3). This mixing controls a number of the NMR phenomena reviewed below, including overtone NMR, heteronuclear dipolar splittings, and zero field NMR.

2.3 Level Populations

Since $I > \frac{1}{2}$ spins have more than two Zeeman levels, it is necessary to use two or more independent parameters for the description of their relative populations. In thermal equilibrium, the high-field population pattern is as illustrated in Figure 5(a) for $I = 1$ or Figure 5(c) for $I = \frac{3}{2}$. The populations of the levels m are then given by $(1 - m\hbar\omega_0/kT)/(2I + 1)$, which is the Boltzmann distribution in the high-temperature approximation. This is called Zeeman order, because the populations are determined by the Zeeman interaction. It is characterized by uniform population increments between adjacent levels. The application of rf pulses causes deviations from the Boltzmann distribution. When these deviations are such that the Zeeman pattern is retained, we can introduce a meaningful ‘spin temperature’ replacing T in the distribution expression above. The distribution pattern can also be of the type depicted in Figure 5(b) and (d). This is called quadrupolar order, because the deviations from the average population follow the $m^2 - \frac{1}{3}I(I + 1)$ dependence associated with the quadrupolar interaction [equation (2)]. In general, the population distribution of spins $I = 1$ is a combination of the two. Unlike Zeeman order, quadrupolar order does not contribute to the z magnetization. In thermal equilibrium,

quadrupolar order is negligible, because the population differences associated with it are ν_0/ν_Q times smaller than those of equilibrium Zeeman order.

For spins with $I \geq \frac{3}{2}$, more types of population distribution need to be considered. An important example is the $I = \frac{3}{2}$ configuration illustrated in Figure 5(e). This arrangement can be viewed as Zeeman order in which the $m = \pm\frac{1}{2}$ populations are equilibrated and do not contribute to the z magnetization (e.g., as a result of selective saturation of the central transition), whereas the equilibrium population difference of the $m = \pm\frac{3}{2}$ levels and their contribution to the z magnetization is retained. For later reference, we call this ‘triple quantum order’.

2.4 Relaxation

Spin relaxation is caused by randomly fluctuating interactions (see also *Relaxation: An Introduction and Relaxation Theory for Quadrupolar Nuclei*). In the case of quadrupolar nuclei, the fluctuations can be electric (due to a time-dependent size or orientation of the EFG) or magnetic (due to fluctuating chemical shifts, dipole–dipole interactions, or interactions with unpaired electrons). When caused by random molecular motions or lattice vibrations, the electric fluctuations usually dominate, since in most cases the quadrupolar interaction is stronger than the magnetic dipolar interactions and chemical shifts.⁶ On the other hand, a magnetic relaxation mechanism mostly prevails in the presence of conduction electrons¹⁴ or in structures containing paramagnetic centers

Figure 4 Energy levels of a spin $I = \frac{3}{2}$ in a coexisting electric field gradient and a magnetic Zeeman field, calculated for varying Larmor frequency ω_0 and quadrupolar frequency ω_Q . The gradual change of these parameters, from the NQR limit ($\omega_0 = 0$) on the left to the NMR limit ($\omega_Q = 0$) on the right, is shown in the curves at the top. The EFG is assumed to be axially symmetric. The corresponding energies of the spin states are shown for two relative orientations of the symmetry axis q of the EFG and the Zeeman field B_0 . The magnetic quantum numbers are indicated for the NQR and NMR limits (m_Q is quantized along q ; m_Z is quantized along B_0)

such as superconducting oxide materials (see *High Temperature Superconductors*).

Longitudinal spin–lattice relaxation is the process by which nonequilibrium level populations (see Figure 5) revert to thermal equilibrium. Unlike relaxation of spin- $\frac{1}{2}$ nuclei, which involves a single transition probability between two energy levels, relaxation of quadrupolar nuclei is generally characterized by several transition rates. Hence, the relaxation decay is multi-exponential, and cannot be quantified by a single T_1 . For instance, the quadrupole-induced spin–lattice relaxation of a spin $I = 1$ has two principal spin–lattice relaxation times: the conventional T_1 for the return of Zeeman order to the equilibrium populations, and a different time T_{1Q} for the decay of quadrupolar order (see Section 2.3). Spin–lattice relaxation patterns of higher spins are more complex. Provided the initial population distribution has the form of Zeeman order, spin–lattice relaxation has one decay constant for $I = 1$, two for $I = \frac{3}{2}$ or 2, three for $I = \frac{5}{2}$ or 3, etc.¹⁵ In powders, the complexity is compounded with

Figure 5 Level population patterns of spins 1 and $\frac{3}{2}$ according to Zeeman order, quadrupolar order, and ‘triple quantum order’

a dependence of the relaxation time on the orientation of the EFG with respect to the Zeeman field. However, the transition rates are mostly of comparable magnitude, such that an approximate assessment of a global T_1 is not unwarranted. The dependence of T_1 on the correlation time τ_c of the motion follows the general Bloembergen–Purcell–Pound (BPP) or Redfield behavior (see *Relaxation: An Introduction*) given by

$$\frac{1}{T_1} = \omega_Q^2 \left(\frac{a\tau_c}{1 + \omega_0^2\tau_c^2} + \frac{b\tau_c}{1 + 4\omega_0^2\tau_c^2} \right) \quad (5)$$

where the numerical coefficients a and b reflect the amplitudes of the EFG fluctuations, the geometric details of the motion, a dependence on I , and the multiexponential character of the decay. A log–log plot of T_1 versus τ_c has the familiar shape shown in Figure 6, with its minimum around ω_0^{-1} . For relaxation due to lattice vibrations, the equation is cast in different forms reflecting the thermal behavior of the phonons.⁶ A similar expression, with a hyperfine coupling constant instead of ω_Q , holds for magnetically induced relaxation.

As is usually done in BPP-type discussions of the transverse relaxation time, we define T_2 as a measure of the inverse linewidth of the spectrum. (The signal decay in echo experiments, albeit important in deuterium NMR, is outside the scope of this article.) In the slow motion limit, the powder spectra have widths and shapes like those of the examples shown in Figure 3. Hence, $1/T_2$ is approximately equal to ω_Q , except for the central transition of half-integer spins, which has $1/T_2$ of the order of ω_Q^2/ω_0 . In the fast motion limit, the spectra are reduced to motionally narrowed Lorentzian lines having full linewidth at half-maximum equal to $1/\pi T_2$. The majority of the spectral components follow the familiar BPP pattern schematically drawn as the $T_2(\text{other})$ curve in Figure 6. If the relaxation mechanism is quadrupolar, the condition for motional narrowing is $\tau_c \ll \omega_Q^{-1}$, and the T_2 of the narrowed spectrum varies with the correlation time according to

$$\frac{1}{T_2} = c\omega_Q^2\tau_c \quad (6)$$

where the numerical coefficient c depends on the motional model.

Figure 6 Idealized log–log plot of T_1 and T_2 relaxation times versus the correlation time of the motion for a model where the spin relaxation is caused by large-scale fluctuations of the EFG. $T_2(\text{central})$ is the inverse halfwidth of the central transition spectra of half-integer spins; $T_2(\text{other})$ is that of satellite transitions or transitions of integer spins

The effect of quadrupolar relaxation on T_2 of the central transition is markedly different,^{16,17} as is indicated by $T_2(\text{central})$ in Figure 6. A gradual increase in the motional rate (decreasing correlation time) begins to narrow the rigid

limit spectrum when τ_c becomes smaller than the reciprocal linewidth ($\tau_c < (\omega_Q^2/\omega_0)^{-1}$), but for shorter τ_c , the line broadens again, and T_2 passes through a minimum when $\tau_c \approx \omega_0^{-1}$. This T_2 behavior was observed for ^{23}Na in amorphous polymer electrolytes above the glass transition temperature.¹⁸ The T_2 minimum is associated with a dynamic frequency shift^{16,17} (see *Dynamic Frequency Shift* and *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*). Transverse relaxation of the central transition due to unpaired electrons does not differ substantially from the relaxation of the other transitions.

2.5 Typical Values of the Nuclear Quadrupolar Coupling Constant

Table 1 lists typical values of the NQCC (χ), the quadrupolar frequency [ν_Q as defined in equation (1)], and the Larmor frequency (ν_0 in the magnetic field of a 300 MHz spectrometer) for selected nuclei. The data were gathered from various sources in the literature. Unless the quadrupole interaction is drastically reduced by cubic symmetry, the actual NQCCs for a particular nucleus do not usually differ by more than a factor two or three from the quoted value. The multiplication factors in parentheses indicate the ratios between the NQCC of isotopes of the same element. These ratios are fixed by the ratios of their eQ values. The relative magnitudes of ν_Q and

Table 1 Typical Values of Nuclear Quadrupole Coupling Constants (NQCC), Quadrupole Frequencies (ν_Q), and Larmor Frequencies (ν_0)

ν_0 serve as a guide for determining whether a nucleus is better studied by NQR or by NMR.

3 INTERACTION WITH RADIOFREQUENCY FIELDS

The manner in which radiofrequency (rf) pulses affect quadrupolar spins in a high magnetic field depends strongly on the relative magnitudes (in frequency units) of three parameters. One is the rf amplitude $\omega_1 = 2\pi\nu_1 = \gamma B_1$, where B_1 is the strength of the rotating magnetic component of the rf field. The other two are the first-order quadrupolar splitting $\Delta\omega_Q = 2\pi\Delta\nu_Q$ and the difference $\Delta\omega_0 = 2\pi\Delta\nu_0$ between the resonance frequency of the spins and the carrier frequency of the rf pulse. Here, the resonance frequency is the combination of Larmor frequency, chemical shift, and second-order quadrupolar shift. While there are no other ways in which second-order quadrupolar effects impact the performance of rf pulses to a noticeable extent, first-order splittings make a large difference. Consequently, the orientation dependence of $\Delta\nu_Q$ can cause a wide range of responses to a uniform rf pulse when it is applied to a powder sample. To avoid this complication, we limit the discussion in this section to samples with a uniform $\Delta\nu_Q$ as in a single crystal. The distinct experimental conditions and their respective effects on quadrupolar spins are categorized below. The summary is descriptive in nature and is presented without theoretical explanations. For the latter, see Section 5.5. See also *Radiofrequency Pulses: Response of Nuclear Spins*.

3.1 Nonquadrupolar Nuclei

To introduce the rf-related concepts of nutation, spin locking, and population transfer, we first consider the simple example of a vanishing NQCC ($\nu_Q = 0$). In the rotating frame (the axes system that rotates with the frequency of the rf carrier), the rf field is represented by a constant vector $\mathbf{v}_1$ of length ν_1 along x , while the Zeeman field is effectively reduced to an offset vector $\Delta\mathbf{v}_0$ of length $\Delta\nu_0$ along z (see the axis diagram in the top portion of Figure 7). The magnetization precesses about the ‘effective field’, which is represented by the vector $\mathbf{v}_{\text{eff}}$. We distinguish the two limiting cases of (a) irradiation close to resonance, $\Delta\nu_0 \ll \nu_1$, and (b) irradiation far off resonance, $\Delta\nu_0 \gg \nu_1$. These cases are also represented in the more schematic illustration in the lower part of Figure 7, where the effective range of the rf field is represented in the frequency domain by a shaded rectangle of width of order ν_1 centered at the carrier frequency. In NMR terminology, the precession induced by a pulse of type (a) is referred to as ‘nutation’. In general, this term relates to precessions caused by rf irradiation and that begin with the spins in thermal equilibrium. In case (a), the nutation is in the (y, z) plane, and takes place with a nutation frequency equal to the rf amplitude, $\nu_{\text{nut}} = \nu_1$. If before the application of the pulse the spins have been prepared so that they point in the x direction of the rotating frame, they will be spin locked by a pulse of type (a).

No nutation or excitation is induced by a far-off-resonance pulse, but we can speak of spin locking in its presence. Namely, the direction of the effective field $\mathbf{v}_{\text{eff}}$, which is nearly parallel to z in case (b), can be viewed formally as a spin locking field for z magnetization. This notion is a

Figure 7 Top: Rotating frame representation of an rf field of amplitude ν_1 (in frequency units) and a resonance offset $\Delta\nu_0$. This representation is adequate for a nonquadrupolar spin system, either $I = \frac{1}{2}$ or $I > \frac{1}{2}$. Bottom: Schematic frequency domain representation of rf irradiation of nonquadrupolar spins. The rf excitation profile is indicated by a shaded rectangle centered at the rf carrier frequency and extending over the approximate excitation range of the rf field. The limiting cases are (a) on-resonance rf ($\Delta\nu_0 \ll \nu_1$) and (b) off-resonance rf ($\Delta\nu_0 \gg \nu_1$)

useful starting point for the description of an adiabatic passage that occurs when $\Delta\nu_0$ is slowly changed from one side of resonance to the other. During an adiabatic passage, the spins remain spin locked along $\mathbf{v}_{\text{eff}}$ and rotate together with it from z through x to $-z$. Eventually, this results in population inversion of the Zeeman levels. In the case of $I = \frac{1}{2}$ the passage transfers the population of the $\frac{1}{2}$ level to the $-\frac{1}{2}$ level and vice versa. The criterion for adiabaticity is that the parameter

$$\alpha = \frac{\omega_{\text{nut}}^2}{d\Delta\omega_0/dt} \quad (7)$$

must be larger than 1. If the passage is sudden ($\alpha \ll 1$), the magnetization remains in the original direction and no populations are transferred. If it is intermediate ($\alpha \approx 1$), the magnetization ends up in a direction that is not spin locked.

3.2 Spin-1 Nuclei

For the visualization of rf fields in the presence of quadrupolar interactions, we can no longer resort to a simple three-dimensional vector picture. Instead, we shall review the

Figure 8 Schematic frequency domain representation of rf irradiation of quadrupolar spins $I = 1$ and $\frac{3}{2}$. The rf ranges are indicated as in Figure 7. The response of the spins to the irradiation depends on the position of the carrier frequency and on the width of the excitation range with respect to the quadrupole-split NMR peaks shown at the top

various aspects of rf irradiation with the help of the illustrations in the frequency domain shown in Figure 8.

3.2.1 Nutation

When $I = 1$, we distinguish five special cases denoted (a)–(e):

3.2.1.1 Case (a). The excitation is nonselective when ν_1 is larger than both $\Delta\nu_Q$ and $\Delta\nu_0$. The two allowed transitions (see the $I = 1$ portion of Figure 2) are then simultaneously excited. As in the $\nu_Q = 0$ case (Figure 7), the nonselective pulse induces nutation with frequency $\nu_{\text{nut}} = \nu_1$. However, following the pulse, the spin system will not continue to behave like a nonquadrupolar nucleus. Excitation by two or more pulses, with quadrupolar interactions acting in the intervals, can create as many as eight distinct spin state configurations, of which polarizations along x , y , and z are only three examples.

Two other kinds of spin states are of particular interest. These are ‘quadrupolar order’, which was discussed in the previous section (see Figure 5), and ‘double quantum coherence’, which is a quantum mechanical state that can

be thought of as a linear combination of $m = +1$ and -1 states. Although double quantum coherence is not observable in the form of nuclear magnetization, it has some similarity to regular transverse magnetization (‘single quantum coherence’) in that it has x and y components that undergo precession under frequency offset. Unlike single quantum coherence, the double quantum precession frequency is twice the offset frequency. For density matrix representations of these coherences, see Section 5.4.

The most prominent nonselective pulse sequence is the quadrupolar echo sequence, also called solid echo sequence. It consists of two out-of-phase 90° pulses separated by an interval τ : $90^\circ_x - \tau - 90^\circ_y$. The spin dephasing due to first-order quadrupolar effects is refocused by the second pulse, and an echo is formed at time τ following the second pulse.

3.2.1.2 Case (b). When ν_1 is small ($\nu_1 \ll \Delta\nu_Q$) and the rf profile does not overlap with any of the transitions [Figure 8(b) shows two examples], the spins are not excited, except in case (c) below.

3.2.1.3 Case (c). A weak rf field ($\nu_1 \ll \Delta\nu_Q$) applied at the exact midpoint between the two spectral lines ($\Delta\nu_0 = 0$) induces $\Delta m = 2$ transitions directly between the $m = +1$ and -1 states, while leaving the $m = 0$ state unaffected. This effect was indicated in Figure 2 as the forbidden double quantum transition. It can be understood in terms of a second-order perturbation of the first-order quadrupolar interaction by the rf interaction (see Section 5.5). It results in a double quantum nutation frequency given by¹⁹

$$\nu_{2Q} = 2\nu_1^2 / \Delta\nu_Q \quad (8)$$

A pulse of duration $\tau_p = 1/4\nu_{2Q}$ is a double quantum 90° pulse. It transforms Zeeman order into a state of double quantum coherence. A double quantum 180° pulse inverts the populations.

3.2.1.4 Case (d). When the rf carrier is slightly off resonance, no double quantum excitation occurs, despite the fact that the offset may be less than the rf amplitude ($\nu_{2Q} \ll \Delta\nu_0 < \nu_1 \ll \Delta\nu_Q$).

3.2.1.5 Case (e). Selective excitation of one of the allowed transitions ($-1 \leftrightarrow 0$ or $0 \leftrightarrow +1$) is caused by a weak rf field applied at its resonance frequency. The corresponding nutation frequency is given by $\nu_{\text{nut}} = \nu_1 \sqrt{2}$.

3.2.2 Spin Locking

Each of these five forms of rf irradiation is associated with one or more spin locked spin configurations. If the rf field is applied along x in the rotating frame, the following spin states are spin locked under the various conditions: nonselective irradiation (a) spin locks transverse spin polarization along x ; off-resonance irradiation (b) and (d) spin lock Zeeman and quadrupolar order; double quantum irradiation (c) spin locks double quantum coherence of type x ; and selective irradiation of an allowed transition (e) spin locks the corresponding single quantum coherence.

3.2.3 Population Transfer

Adiabatic passages, similar to the population inversion described in Section 3.1, can occur for quadrupolar spins

$I = 1$ when the rf profile crosses over from one side of a transition to the other. For instance, a slow passage between the two situations drawn for case (b) in Figure 8 causes population exchange between the levels $m = 0$ and -1 , and thus transforms pure Zeeman order to a combination of Zeeman and quadrupolar order. Such a passage is materialized by a slow sweep of $\Delta\nu_0$, which can in turn be done by sweeping of the carrier frequency or of the magnetic field. Another possibility is the sweeping of $\Delta\nu_Q$. Because of its orientation dependence, the quadrupolar splitting can easily be varied by simply turning the sample. The passage is adiabatic if the change in $\Delta\nu_Q$ is sufficiently slow for the condition $\alpha > 1$ to be satisfied, with the adiabaticity parameter defined as $\alpha = \omega_{\text{nut}}^2 / (d\Delta\omega_Q/dt)$. Magic angle spinning (MAS) is a particularly effective method for $\Delta\nu_Q$ sweeping, since $\Delta\nu_Q$ of any crystallite experiences two or four zero-crossings per rotation cycle. (This is consistent with the $\Delta\nu_Q$ averaging to zero by MAS.) If the spinning rate is denoted by ν_R , the adiabaticity parameter is roughly equal to

$$\alpha \approx \frac{\nu_1^2}{\nu_R \nu_Q} \quad (9)$$

3.3 Nuclei with Half-Integer Spin

3.3.1 Nutation ($I = \frac{3}{2}$)

The response of a spin $I = \frac{3}{2}$ to the application of rf pulses is in many respects similar to that of $I = 1$, but there are a few differences to be pointed out. We again distinguish among five special cases illustrated in the bottom half of Figure 8.

3.3.1.1 Case (f). When ν_1 covers the entire spectrum, the excitation is nonselective and the nutation frequency is $\nu_{\text{nut}} = \nu_1$. The spin dynamics of sequences with more than one pulse is even richer than for $I = 1$ nuclei, since there are 15 independent spin states for $I = \frac{3}{2}$ (see Section 5.4). The nonselective solid echo sequence $90^\circ_x - \tau - 90^\circ_y$ refocuses first-order quadrupolar dephasing as in the case of $I = 1$.

3.3.1.2 Case (g). There is no excitation when the rf profile does not overlap with any transition (but see Section 5.5).

3.3.1.3 Case (h). A weak rf pulse applied at the exact midpoint between the satellite transitions induces a triple quantum excitation^{20,21} between $m = -\frac{3}{2}$ and $\frac{3}{2}$ with a nutation frequency given by $\nu_{3Q} = \frac{3}{2}\nu_1^3/\Delta\nu_Q^2$. The resonance conditions for triple quantum transition and for the allowed central transition do not coincide exactly, because the two transitions have different second-order shifts. The triple quantum excitation is quenched when the carrier frequency is slightly off resonance ($\Delta\nu_0 > \nu_{3Q}$), but when $\Delta\nu_Q$ is not much larger than ν_1 , the excitation is effective for $\Delta\nu_0 \lesssim \nu_1$.

3.3.1.4 Case (i). A weak pulse ($\nu_1 < \Delta\nu_Q$) with an rf profile that overlaps with the central transition induces selective excitation of the latter. The nutation frequency for this transition is $\nu_{\text{nut}} = 2\nu_1$.

3.3.1.5 Case (j). Selective excitation of the satellites occurs with a nutation frequency $\nu_{\text{nut}} = \nu_1\sqrt{3}$. Note that, unlike selective excitation of the narrow central transition, selective excitation of satellite transitions cannot be achieved simultaneously for all crystallites in a powder sample.

3.3.2 Spin Locking ($I = \frac{3}{2}$)

The spin states of $I = \frac{3}{2}$ nuclei that are spin locked under the various modes of rf irradiation follow a pattern similar to that of $I = 1$, and do not need to be discussed in detail. However, the case of selective irradiation of the central transition [case (i)] deserves some special attention. During an rf pulse of this type, two spin state configurations can be spin locked. One is the population difference of the $m = \pm\frac{3}{2}$ levels illustrated as ‘triple quantum order’ in Figure 5(e). For convenience, we give it the shorthand notation T_z to indicate that it is associated with the triple quantum transition and that it contributes to z magnetization. The other is single quantum coherence of the central transition, denoted by C_x , which is a linear combination of states $m = \frac{1}{2}$ and $-\frac{1}{2}$ contributing to x magnetization. Density matrix representations of T_z and C_x are given in Section 5.5. When a type (i) pulse is applied to spins $I = \frac{3}{2}$ that are initially in thermal equilibrium, two things happen simultaneously: the T_z portion of the spin state is spin locked while the central transition portion undergoes nutation. However, if the central transition portion is prepared in the C_x state by appropriately chosen preparatory pulses, simultaneous spin locking of T_z and C_x can be achieved.

3.3.3 Population Transfer ($I = \frac{3}{2}$)

An adiabatic passage caused by zero-crossing of $\Delta\nu_Q$ in a slowly rotating sample transfers a spin locked T_z state to C_x , and vice versa. As mentioned above for $I = 1$, magic angle spinning is an efficient method for inducing these passages. The criterion for adiabaticity is again $\alpha > 1$, with α as defined as in equation (9).²² The populations of the $\pm\frac{3}{2}$ states can also be transferred to the $\pm\frac{1}{2}$ states by adiabatic sweeping of $\Delta\omega_0$.²³

3.3.4 Central Transition ($I \geq \frac{3}{2}$)

Similar concepts can be applied to half-integer spins with $I > \frac{3}{2}$, but, other than the general case of central transition excitation, they will not be discussed further. The frequency of nutation of the central transition induced by nonselective irradiation, as exemplified by case (f) in Figure 8, is given by $\nu_{\text{nut}} = \nu_1$. On the other hand, when the excitation is selective as in case (i), the general formula for the nutation frequency is

$$\nu_{\text{nut}} = (I + \frac{1}{2})\nu_1 \quad (10)$$

This effective enhancement of the rf amplitude has obvious consequences for the choice of pulse length for obtaining optimum signal intensity in a selective single pulse excitation experiment. For $I = \frac{3}{2}$ the apparent 90° pulse is a nominal 45° pulse. Likewise, for $I = \frac{5}{2}$, it is 30° , and so on. An additional result of selective excitation is that it reduces the intensity of the resulting central transition signal. If the signal (not including the satellites) following a nonselective pulse of length τ_p can be described by

$$S(\tau_p) = S_0 \sin \omega_1 \tau_p \quad (11)$$

then the signal following a selective pulse is

Figure 9 Central transition signal intensity following excitation by a single rf pulse of nominal flip angle $\omega_1 \tau_p$, where τ_p is the duration of the pulse, plotted for the limits of nonselective ($\omega_1 \gg \Delta\omega_Q$) and selective ($\omega_1 \ll \Delta\omega_Q$) irradiation

$$S(\tau_p) = \frac{S_0}{I + \frac{1}{2}} \sin[(I + \frac{1}{2})\omega_1 \tau_p] \quad (12)$$

The flip angle dependence according to equations (11) and (12) is plotted in Figure 9 for $I = \frac{3}{2}$ and $\frac{5}{2}$.

So far, we have avoided discussion of rf amplitudes that are intermediate between selective and nonselective excitation ($\nu_1 \approx \nu_Q$). However, this situation is often encountered in practice. The response of the spin system to intermediate rf amplitudes is more complex than in the limiting cases. For details see *Nutation Spectroscopy of Quadrupolar Nuclei*. A significant feature is that for relatively small flip angles ($\omega_{\text{nut}} \tau_p < \pi$), the intermediate $S(\tau_p)$ functions fall between the limits of selective and nonselective pulses. Hence, since the initial slopes of the functions of equations (10) and (11) are identical, the signal intensity following very short pulses is independent of the size of the quadrupolar interaction. This result has important implications for the quantitative interpretation of NMR signal intensities.

4 EXPERIMENTAL METHODS

Methods for NMR detection of quadrupolar nuclei in solids are surveyed in this section. The emphasis is not on the achievements of the applications of these techniques, but rather on the underlying spectroscopic principles and their interrelations. Consequently, this section frequently refers to the basic spin properties introduced in the previous sections. The survey is divided in subsections on deuterium, ^{14}N , and half-integer spins, reflecting the fact that in practical

applications the choice of a workable NMR method is usually dictated by the size of the NQCC and by the presence or absence of a central transition. The section concludes with a brief introduction to zero field NMR.

4.1 Deuterium

Detailed theoretical and experimental aspects of solid state NMR of deuterium are covered in the articles *Deuterium NMR in Solids*; *Liquid Crystalline Samples: Deuterium NMR*; *Liquid Crystalline Samples: Relaxation Mechanisms*; *Membranes: Deuterium NMR*, and *Polymer Dynamics and Order from Multidimensional Solid State NMR*. Applications to polymers were reviewed by Spiess in 1985.⁷ Key references to the literature can also be found in these articles.

4.1.1 First-Order Spectra

The most intensively studied first-order quadrupolar spectra are those of deuterium. This is partially due to the chemical importance of the hydrogen atom and the advantages of selective deuteration, but there is also a fortuitous combination of spectroscopic conditions. Deuterium is among the few quadrupolar nuclei for which the total width of the spectra is never much larger than 200 kHz. This ensures that the deuterium spectrum of any chemical structure can be detected within a practical bandwidth and the spins can be excited with essentially nonselective pulses. In addition, the spectra are not appreciably affected by second-order quadrupolar shifts, dipolar broadenings, or chemical shifts, because in the case of deuterium all these contributions are at least two orders of magnitude smaller than ν_Q . Another advantage is that the powder lineshapes of the first-order spectra of spin-1 nuclei are composed of only two spectral transitions, and are thus less complex than those of higher-spin nuclei (see Figure 2 and 3). These circumstances allow the observation of the sometimes subtle lineshape changes caused by nonrandom distributions of molecular orientation (as in liquid crystalline materials) or by rapid random reorientations of the EFG tensor. In fact, the bulk of solid state deuterium NMR work is focused on the elucidation of molecular motions, particularly in polymers, liquid crystals, and adsorbed molecules. In combination with a judicious use of relaxation times and the application of two-dimensional methods (see below), motions with correlation times from nanoseconds to seconds can be characterized.

4.1.2 Zeeman Order and Quadrupolar Order

In the so-called spin-alignment experiment,⁷ the spins are prepared in a state of quadrupolar order (see Section 2.3), where they can be held for a time as long as T_{1Q} permits. During that time, chemical exchange can modify the level populations. Two-dimensional methods use this and a similar Zeeman-order scheme for characterization of slow molecular dynamics.

4.1.3 Pulse Sequences

Although deuterium spins can be excited with a nonselective pulse, the FID following a single 90° excitation pulse is short and largely undetectable because of the receiver dead time.

Therefore, the signals need to be created with the solid echo sequence, $90^\circ_x - \tau - 90^\circ_y$, where the second half of the echo serves as the FID for further data processing. The dependence of the signal on τ provides an extra experimental parameter for the study of motions. Quadrupolar order is created with the Jeener–Broekaert sequence, $90^\circ_x - \tau - 45^\circ_y$,²⁴ and detected with a 45° read-out pulse.

4.1.4 Double Quantum Transitions

Since the double quantum transition frequency is not shifted by the quadrupolar interaction, it is useful for measurements of the chemical shift tensor²⁵ or, in conjunction with MAS, the isotropic chemical shift,²⁶ and also for achieving high resolution in imaging.²⁷ In fact, the double quantum coherence precesses in the rotating frame with twice the offset frequency, and thus has an enhanced sensitivity to small changes in the resonance frequency. Because double quantum coherences are not directly observable, their time dependence has to be measured in a 2D-type experiment where the spins are allowed to evolve for a stepwise incremented time t_1 , at the end of which they are detected with a nonselective read-out pulse that transfers double quantum coherence to observable signals. The double quantum state can be prepared by a variety of methods:²⁸ a double quantum excitation pulse [Figure 8(c)], double quantum cross polarization (a method where Hartmann–Hahn contact between, say, protons and deuterons is established by adjusting ν_1 of the protons to be equal to ν_{2Q} given by equation (8)),²⁹ two nonselective pulses,²⁶ or three nonselective pulses.²⁷

4.1.5 Double Quantum Decoupling

Effective dipolar decoupling of deuterium from other nuclei by nonselective irradiation of the allowed transitions requires a very high rf intensity, which is difficult to produce in practice. However, decoupling can also be achieved through stirring of the $m = +1$ and -1 states by double quantum excitation.¹⁹ It does not matter that this method does not stir the $m = 0$ state, because the latter is magnetically ‘neutral’ and does not contribute to dipolar broadening. The provision that the irradiation must be close to the double quantum resonance frequency (see Section 3.2.1.4) presents no practical problem, since the resonance condition is only affected by chemical shifts and second-order quadrupolar shifts.

4.1.6 Magic Angle Spinning

The similarity between the orientational dependence of the first-order quadrupolar splitting and that of CSA implies that MAS removes quadrupolar broadening in deuterium spectra of powders in the same way in which it narrows CSA broadening. However, since rotation speeds are much smaller than the width of the spectrum, the centerband of the MAS spectrum is always accompanied by a large number of sidebands, the envelope of which resembles the static lineshape.^{30,31} Owing to the absence of an isotropic first-order shift, the position of the centerband is entirely determined by isotropic chemical shifts and second-order quadrupolar shifts.

4.2 Nitrogen-14

With the exception of chemical structures where near-cubic site symmetry reduces the NQCC to small values,³² first-order ^{14}N spectra of powders are too broad for detection by NMR. Consequently, direct measurement of ν_Q and η of most compounds is feasible only by NQR spectroscopy. The spin- $\frac{1}{2}$ isotope ^{15}N is usually preferred for solid state NMR studies, despite its low natural abundance (0.365%). (See also *Nitrogen NMR*.) Nevertheless, ^{14}N nuclei can be detected by several indirect NMR methods that circumvent the bandwidth problems related to the first-order broadening.

4.2.1 Double Quantum Transitions

The absence of first-order quadrupolar effects on double quantum resonance frequencies reduces the spectral width to within practical detection limits. However, double quantum spectroscopy of ^{14}N is much more difficult to perform than the corresponding deuterium experiments (see above). For instance, the method of detection of double quantum coherence by way of coherence transfer to the allowed transitions is not applicable to ^{14}N , because the allowed transitions are inaccessible. Instead, double quantum coherence can be observed indirectly via cross polarization to neighboring protons.³³

4.2.2 Overtone NMR

As was mentioned in connection with Figure 4 in Section 2.2, a strong quadrupolar interaction causes the admixture of, e.g., some $m = 0$ character in the $m = 1$ and -1 states. As a result, the nominally forbidden $\Delta m = 2$ transition between the $m = -1$ and 1 levels acquires some degree of $\Delta m = 1$ character and becomes weakly allowed. Overtone NMR is the direct excitation and observation of this transition. It is performed at twice the Larmor frequency, $2\nu_0$, which is the frequency corresponding to the energy difference between the $m = \pm 1$ levels (see Figure 2). Although both overtone excitation and double quantum excitation (Section 2.3) induce forbidden transitions between the $m = \pm 1$ levels, they are based on entirely different principles: overtone NMR makes use of the second-order quadrupolar perturbation of Zeeman levels, but is otherwise a direct detection method. On the other hand, double quantum NMR does not rely on mixing of the Zeeman levels, but rather on a second-order rf perturbation of the quadrupole energy levels (see Section 5.5). The practical incentive for overtone NMR is obviously that the resonance frequencies are not shifted by first-order quadrupolar effects, an advantage shared with double quantum NMR. For further details, see *Overtone Spectroscopy of Quadrupolar Nuclei*.

4.2.3 Heteronuclear Dipolar Splitting

The single crystal NMR spectrum of, say, a ^{13}C nucleus coupled by dipolar interaction to a nearby ^{14}N nucleus is split into three lines corresponding to the magnetic states $m = -1, 0, 1$ of the $I = 1$ spin. In first approximation, the magnetic moments associated with these ^{14}N states are aligned with the Zeeman field and have values proportional to m . This has two consequences: the ^{13}C triplet is symmetric,

and the dependence of their spectral positions on the crystal orientation is such that MAS removes the dipolar broadening in powders. However, in the presence of a large NQCC, the ^{14}N spins are no longer quantized along the Zeeman field, as was pointed out in our discussion of Figure 4. This changes the directions and magnitudes of the magnetic moments of the three eigenstates, and, hence, the symmetry of the triplet and the orientation dependence of its peak positions. These effects were first observed in a single crystal.³⁴ The modified orientation dependence also prevents complete narrowing of the dipolar broadening by MAS.³⁵ Provided ν_Q is sufficiently small in comparison to the ^{14}N Larmor frequency ν_0 , the residual splitting of the ^{13}C MAS peak can be evaluated by perturbation theory. It was shown to be of the order $\nu_D \nu_Q / \nu_0$, where ν_D is the magnitude of the dipolar interaction. The literature dealing with these phenomena is summarized in a review article by Harris and Olivieri.³⁶ (See *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14.*)

4.2.4 Population Transfer

Slow MAS rotation under continuous rf irradiation of ^{14}N nuclei induces spin flips through adiabatic transformations among the m states (see Section 3.2). This effect has found application in a REDOR-type method for ^{13}C – ^{14}N distance determination.³⁷ The principle of regular REDOR experiments as applied to $I = S = \frac{1}{2}$ spin pairs is as follows. The FID signal of the S spins decays as a result of the dipolar interaction between I and S , but MAS refocuses the dipolar dephasing and creates a rotational echo at the end of a full rotor period. The refocusing is undone if a 180° pulse is applied to the I spins, flipping them from one m state to another at some time during the rotor cycle. This causes a rotational echo signal reduction of S , which can be analyzed to determine the I – S atomic distance (see *REDOR and TEDOR*). The REDOR experiment cannot be applied in this form when the I spins are ^{14}N , because the 180° pulse must be nonselective to be effective. Instead, one can bring about the desired m flips by population transfer under adiabatic sample spinning conditions (transfer of populations in double resonance or TRAPDOR).³⁷

4.3 Nuclei of Half-Integer Spin

Detailed theoretical and experimental aspects of solid state NMR of half-integer spins are covered in the articles *Double Rotation; Dynamic Angle Spinning; High Speed MAS of Half-Integer Quadrupolar Nuclei in Solids; High Temperature Superconductors; Nutation Spectroscopy of Quadrupolar Nuclei; Quadrupolar Nuclei in Glasses*, and *Variable Angle Sample Spinning*. The literature on this subject before 1993 is summarized in an extensive review article by Freude and Haase.⁶ Key references to the literature can also be found in these articles.

4.3.1 Static First-Order Spectra

Examples of simulated first-order quadrupolar lineshapes of half-integer nuclei in static samples were shown in Figure 3. Experimental spectra are, however, rarely reported. Their detection necessitates excitation by more than one pulse, since the receiver deadtime renders the FID following a single

pulse largely undetectable. If nonselective pulses are feasible, a quadrupolar echo sequence identical to that described above for deuterium can be applied to refocus the signal and to allow ‘zero-time resolution’. This has been demonstrated for $I = \frac{3}{2}$ ³⁸ and $\frac{5}{2}$.³⁹ Another approach is the so-called two-pulse free induction decay.⁶ It is a 2D experiment consisting of two nonselective pulses. The first creates coherences of $\Delta m = 1$ transitions that evolve with frequencies equal to multiples of $\Delta\nu_Q$. After a time t_1 , the second pulse is applied to transfer the coherences to the central transition, which can easily be detected. Central transition coherences during t_1 are suppressed by phase cycling, and the 2D spectra of spins $\frac{5}{2}$ are simplified in that they are dominated by the first satellite as a result of less effective coherence transfer from the second satellites.

4.3.2 MAS of First-Order Spectra

The orientational dependence of $\Delta\nu_Q$ is such that it allows narrowing of first-order powder spectra by MAS. Compared with deuterium, this experiment is more demanding in terms of spinning stability, because the spectra are generally broader. Jakobsen and co-workers (see *High Speed MAS of Half-Integer Quadrupolar Nuclei in Solids*) have succeeded in obtaining highly resolved sideband patterns with ν_Q as large as 1 MHz for $I = \frac{3}{2}$ and 0.5 MHz for $I = \frac{5}{2}$. Fine structure of the sidebands due to second-order shifts and sideband envelopes can be analyzed to obtain detailed information on the spin system.

4.3.3 Multiple Quantum Coherence

Triple quantum coherence can be excited with an on-resonance selective pulse,²⁰ as indicated in Figure 8(h). The method of pulsed multiple quantum NMR (much-practised in one- and multidimensional NMR²⁸) was first demonstrated in 1975 by Hatanaka et al.,⁴⁰ who created ^{27}Al ($I = \frac{5}{2}$) double quantum coherence in a single crystal by application of two consecutive selective pulses at different allowed transition frequencies.

4.3.4 Echoes and Multiple Pulse Experiments

Numerous combinations of nonselective and selective, on- and off-resonance pulses have been reported for the excitation, refocusing, coherence transfer, or selective detection of single and multiple quantum coherences. This diverse subfield of quadrupolar NMR has been reviewed by Sanctuary and Halstead⁴¹ and by Freude and Haase.⁶

4.3.5 Spin Counting

In NMR, the signal intensity is proportional to the number of spins that give rise to it (see *Quantitative Measurements*). It can thus be used for quantitative analysis, provided the signals of the unknown sample and a reference sample are excited and detected under comparable conditions. In the case of NMR of half-integer spins, three complicating factors need to be considered.

1. When only the central transition is observed, the signal is reduced by a factor reflecting the relative intensities of the

central and satellite transitions. For a given spin I these are given by

$$S_{m \leftrightarrow m+1} \propto I(I+1) - m(m+1) \quad (13)$$

The relative intensities and the percentages of the total intensity represented in the central transition are listed in Table 2. The appropriate reduction factor needs to be accounted for when signal intensities of solids are compared with a liquid reference sample, because in liquids all the transitions are observed. A corresponding signal reduction is also observed when defects are introduced in cubic crystals: at perfectly cubic sites the full signal is detected because ν_Q vanishes, but defects lower the symmetry, increase ν_Q , and wipe out the satellites.⁵

2. The NQCC can be so large that even the second-order effects broaden the central transition beyond the detection limit. Aluminum-27 NMR is particularly susceptible to this effect, since minor chemical modifications can drastically enhance the NQCC (Table 1). A classic example is the disappearance of ²⁷Al signal due to atoms near the surface of high-surface-area alumina, resulting in an inverse correlation between the signal intensity and the specific surface area.⁴² In studies of disordered systems, it is always good practice to supplement ²⁷Al NMR spectra with a quantitative assessment of the percentage of nuclei that are represented in the spectrum. Sometimes, more useful information on the nature of a sample is revealed by a determination of the amount of 'NMR-invisible' Al than by the interpretation of an observed but nonrepresentative lineshape.
3. For quantitative comparison between different signals, it is imperative to work with excitation pulses of sufficiently small flip angle to ensure that the signal intensity does not depend on $\Delta\nu_Q$ (compare Figure 9). The largest deviation is between purely selective and nonselective excitations. To keep it under 5%, the nominal flip angle (i.e., the nutation angle if the pulse were applied to a liquid sample) must be smaller than 18°, 11°, and 8° for $I = \frac{3}{2}$, $\frac{5}{2}$, and $\frac{7}{2}$, respectively. For deviations less than 10%, the flip angles must be limited to 25°, 15°, and 11°, respectively.

4.3.6 Nutation Spectroscopy

Nutation spectroscopy in its simplest form is the study of the signal intensity following a single pulse, measured as a function of the length of the pulse. Fourier transformation in 2D fashion yields a nutation spectrum that reflects the distribution of nutation frequencies ν_{nut} of the spins during the pulse. Nutation spectroscopy applied to the central transition provides indirect information on the first-order quadrupolar parameters: when $\nu_1 \gg \nu_Q$, the nutation spectrum has a peak

at ν_1 ; when $\nu_1 \ll \Delta\nu_Q$ the peak is at $(I + \frac{1}{2})\nu_1$ [see equation (12) and Figure 9]. Nutation spectra of powders obtained with intermediate rf amplitudes ($\nu_1 \approx \nu_Q$) feature characteristic powder lineshapes that are sensitive to the ratio ν_Q/ν_1 and to η . For further details, see *Nutation Spectroscopy of Quadrupolar Nuclei*.

4.3.7 Second-Order Spectra: Static, MAS, and VAS

The central transition spectra of powder samples have received a great deal of attention. Figure 10 shows the spectral lineshapes for various values of η , without and with MAS. The shapes of the spectra do not depend on I , but their widths do. For that reason, the lineshapes in Figure 10 are plotted on a universal frequency scale, where one unit represents a frequency increment of

$$A = \frac{1}{9}[I(I+1) - \frac{3}{4}] \frac{\nu_Q^2}{\nu_0} \quad (14)$$

The symmetry of the orientation dependence of the second-order shift differs from that of first-order effects such as CSA, dipolar interaction, and first-order quadrupolar splitting. Consequently, complete line narrowing is not achieved with MAS, as may be seen in Figure 10. Nevertheless, MAS spectra are still preferable to static spectra, not only because the quadrupolar pattern is three to four times narrower, but also because CSA and dipolar broadenings are removed. Chemical shift resolution of MAS spectra improves dramatically when the magnetic field is increased. Since second-order broadening and chemical shift are proportional to $1/\nu_0$ and ν_0 , respectively, the resolution scales as ν_0^2 . High spinning speeds also improve

Figure 10 Central transition lineshapes of half-integer spins broadened by the second-order quadrupolar effect, calculated for static and fast MAS conditions. The frequency scale is in units of A , which is defined in equation (14)

Table 2 Relative Intensities of the Transitions of Half-Integer Quadrupolar Nuclei

I	Relative intensities	Central transition (%)
3/2	3:4:3	40
5/2	5:8:9:8:5	25.7
7/2	7:12:15:16:15:12:7	19.0
9/2	9:16:21:24:25:24:21:16:9	15.2

resolution, because they prevent overlap of sidebands. Another approach is the technique of variable angle spinning (VAS), in which the samples are rotated about an axis that does not necessarily make the magic angle with the Zeeman field. Certain angles give narrower second-order spectra, but complete narrowing is not obtained. For more details, see *Variable Angle Sample Spinning*.

4.3.8 Narrowing of Second-Order Broadening

The search for methods to remove the second-order quadrupolar broadening culminated in the inventions of two composite sample rotation techniques: DAS⁴³ and DOR.⁴⁴ Both methods succeed in narrowing the lines by making use of the particular orientational symmetry of the shift. For details, see *Double Rotation* and *Dynamic Angle Spinning*. It should be noted that sample rotation does not change the center of gravity of the spectra. Consequently, the spectral position of the narrowed peak is the combination of a chemical shift and an isotropic second-order quadrupolar shift, where the latter is given by

$$\Delta\nu_{\text{iso}}^{(2)} = -\frac{1}{30}[I(I+1) - \frac{3}{4}]\frac{\nu_Q^2}{\nu_0}(1 + \frac{1}{3}\eta^2) \quad (15)$$

More recently, line narrowing has also been achieved in a 2D multiple quantum MAS experiment which does not require composite sample rotation. In this MQMAS method the spins are first excited to a triple quantum coherence state (see Section 3.3.1.3) and are subsequently transferred to central-transition coherence where second-order dephasing is refocused.⁴⁵ See also *Line Narrowing Methods in Solids*.

4.3.9 Heteronuclear Dipolar Splitting

Modifications of dipolar splitting patterns similar to those of nuclei coupled to ¹⁴N (see Section 4.2), are also observed when the neighboring nucleus is of half-integer spin and has a large NQCC. Examples of coupling to ⁶³Cu/⁶⁵Cu, ³⁵Cl/³⁷Cl, and other nuclei have been documented.³⁶

4.3.10 Relaxation

Spin-lattice relaxation does not usually follow a single exponential behavior for the reasons outlined in Section 2.4. Additional complications arise when the T_1 of a central transition is measured by monitoring the signal following saturation. The results depend on whether a single selective saturation pulse or a long saturation comb is applied, and on whether the measurements are done under MAS or static conditions. The apparent T_1 can vary by more than an order of magnitude, depending on the measurement method.⁴⁶ The differences are caused by variations in initial population distributions of the energy levels [compare Figure 5(c) and (e)] and by variability of the effectiveness of spin diffusion between the central transition and satellite transitions of a neighboring nucleus.⁴⁶

4.3.11 Spin Locking and Population Transfer

The x magnetization formed by application of a selective y pulse to the central transition corresponds to the spin state C_x

(see Section 3.3). When spin locked by rf irradiation in the x direction, it decays with the relaxation time $T_{1\rho}$. However, under MAS at slow rates [$\alpha > 1$ with α defined as in equation (9)], the relaxation decay is interrupted by adiabatic population transfer from C_x to T_z (see Section 3.3). As a result, the x magnetization of every nucleus in the sample disappears at the first zero-crossing of its oscillating quadrupolar splitting $\Delta\nu_Q$ and then reappears again at the next zero-crossing. Since different nuclei have their zero-crossings at different times, the total signal decays gradually, but because every nucleus has an even number of zero-crossings per rotor cycle (two or four), the signal grows back toward the end of the first rotor cycle. This pattern is repeated for successive rotor cycles until $T_{1\rho}$ relaxation causes the signal to decay. However, when the rotation rate is so fast that $\alpha \ll 1$, there is no population transfer, and the signal does not decay other than by relaxation. Under rotation at intermediate rates ($\alpha \approx 1$), the passages transform C_x to spin states that are not spin locked, resulting in an irreversible signal decay.²² Another method of population transfer is slow sweeping of the rf carrier frequency. For instance, it can be applied to static $I = \frac{5}{2}$ nuclei for transfer of the populations of the $m = \pm\frac{5}{2}$ states to the $m = \pm\frac{1}{2}$ states in order to obtain a fivefold increase of central transition signal intensity.²³

4.3.12 Cross Polarization

Cross polarization (CP) is the transfer of spin locked polarization (magnetization) from nuclei S to neighboring nuclei I by simultaneous rf irradiation of the two spin systems under matched conditions of the two rf amplitudes ν_{IS} and ν_{IL} . When both I and S are spins $\frac{1}{2}$, the matching requirement is the familiar Hartmann–Hahn condition, $\nu_{IS} = \nu_{IL}$. However, if one or both are quadrupolar nuclei, the appropriate matching condition is that the two nutation frequencies be equal, $\nu_{\text{nut},S} = \nu_{\text{nut},I}$. Thus, for CP of the central transition of half-integer spins I from protons with spin $S = \frac{1}{2}$, the condition is $\nu_{IS} = (I + \frac{1}{2})\nu_{IL}$ (see Section 3.3). The resulting I polarization has the spin locked spin configuration C_x . If the cross polarization is done under MAS conditions (CP MAS), complications arise as a result of the zero-crossings of $\Delta\nu_Q$. The same rf irradiation that establishes the CP matching also serves as a spin lock field for the newly formed central transition polarization. Hence, if the adiabaticity parameter α is in the intermediate range, the signal enhancement is frustrated by the irreversible decay of C_x caused by the nonadiabatic passages (see the preceding paragraph). This can be a reason for poor performance of CP MAS of the central transition.⁴⁷

4.4 Zero Field NMR

The technique of zero field NMR makes use of the connectivity, illustrated in Figure 4, between the spin states at zero Zeeman field (the NQR limit) and at high field (the NMR limit). A sample is mechanically shuttled back and forth between a position where the field is strong and another position where the field vanishes. In this way, the NQR spectrum can be indirectly detected as an NMR signal, with the combined advantages of the higher sensitivity of NMR and the higher spectroscopic resolution of NQR (see Section 2.2). For details, see *Zero Field NMR*.

5 THEORY

5.1 Electric Field Gradient

The nuclear quadrupole interacts with an electric field gradient (EFG). This is the gradient of the electric field created by the charges other than the nucleus under consideration. The isotropic portion of the EFG, i.e., the part that originates from the s electrons, which have a nonvanishing charge density at the site of the nucleus, has no relevance to NMR, because the energy of its interaction with the nuclear charge distribution does not change when the nuclear spin axis changes orientation.⁴ To be sure, the isotropic EFG contributes to isotope shifts in atomic spectra in the form of a 'volume effect' or 'field effect'.^{48,49} However, in the context of NMR, it is customary to ignore its existence. The remaining EFG tensor $\mathbf{V}$ is thus purely anisotropic. It has three principal tensor components, V_{XX} , V_{YY} , and V_{ZZ} , which are associated with a principal axis system (PAS) X , Y , Z (in the present notation, we reserve capital indices for the PAS and let the lower case x , y , z stand for a general axis system). The off-diagonal elements V_{XY} , V_{XZ} , etc., are zero in the PAS. The diagonal elements satisfy the Laplace equation

$$V_{XX} + V_{YY} + V_{ZZ} = 0 \quad (16)$$

reflecting the fact that we ignore the isotropic component. Following the convention

$$|V_{ZZ}| \geq |V_{XX}| \geq |V_{YY}| \quad (17)$$

for the assignment of the three PAS directions, we define the quantity

$$eq = V_{ZZ} \quad (18)$$

and the asymmetry parameter

$$\eta = (V_{YY} - V_{XX})/V_{ZZ} \quad (19)$$

The convention ensures that $0 \leq \eta \leq 1$. When $\eta = 0$, the EFG tensor is axially symmetric about the Z axis: $V_{XX} = V_{YY} = -\frac{1}{2}V_{ZZ}$. For arbitrary η , equations (18) and (19) are solved to give

$$V_{XX} = -\frac{1}{2}(1 + \eta)eq \quad (20)$$

$$V_{YY} = -\frac{1}{2}(1 - \eta)eq \quad (21)$$

One should be aware that many authors prefer the convention $|V_{ZZ}| \geq |V_{YY}| \geq |V_{XX}|$ instead of equation (17) for the assignment of the X and Y axes. The appropriate definition of η is then $(V_{XX} - V_{YY})/V_{ZZ}$, and the signs of η -containing terms in formulas such as equations (3), (20), (21), and (22)–(27) are reversed.

Two kinds of local symmetry at the site of the nucleus dictate the symmetry of the EFG tensor.

1. Cubic point symmetry (including eightfold cubic, sixfold octahedral, and fourfold tetrahedral coordinations) results in $V_{XX} = V_{YY} = V_{ZZ}$, and, hence, by the Laplace equation, $eq = 0$.

2. Axial point symmetry (including structures where the nucleus lies on a threefold, fourfold, fivefold, or sixfold symmetry axis) results in $\eta = 0$.

In ionic crystals, the EFG tensor can be calculated from the known positions and charges of the surrounding ions. However, the actual EFGs experienced by the nucleus are many times larger than the calculated values as a result of distortions of the local electron cloud. The Sternheimer anti-shielding factor accounts for this correction (see *Quadrupolar Interactions*).

Below are formulas for the components of the EFG tensor in a more general axis system x , y , z . To be completely general, we ought to specify three Euler angles for the orientation of x , y , z with respect to X , Y , Z . However, in most NMR experiments, we do not need to know more about the laboratory frame than the direction of the z axis specifying the $\mathbf{B}_0$ field orientation. In such bases, it is sufficient to define the two polar angles θ and ϕ of z with respect to the PAS. In fact, the polar angles represent two of the Euler angles, as is demonstrated in Figure 11, where the directions of x , y , and z are seen to be obtained from X , Y , and Z by rotating the system first about Z over angle ϕ and then about the new y over angle θ . The third Eulerian rotation (about z) is not executed. The transformation depicted in Figure 11 leads to

$$V_{xx} = \frac{1}{2}eq(3\sin^2\theta - 1 - \eta\cos^2\theta\cos 2\phi) \quad (22)$$

$$V_{yy} = \frac{1}{2}eq(-1 + \eta\cos 2\phi) \quad (23)$$

$$V_{zz} = \frac{1}{2}eq(3\cos^2\theta - 1 - \eta\sin^2\theta\cos 2\phi) \quad (24)$$

$$V_{xy} = V_{yx} = \frac{1}{2}eq\eta\cos\theta\sin 2\phi \quad (25)$$

$$V_{xz} = V_{zx} = -\frac{1}{2}eq\sin\theta\cos\theta(3 + \eta\cos 2\phi) \quad (26)$$

$$V_{yz} = V_{zy} = \frac{1}{2}eq\eta\sin\theta\sin 2\phi \quad (27)$$

There are, however, situations where three parameters must be specified to define the relative orientations of the PAS and

Figure 11 Transformation from a principal axis system X , Y , Z to a more general axis system x , y , z . The transformation is accomplished by a rotation through ϕ about Z followed by a rotation through θ about y . θ and ϕ are the polar and azimuthal angles of z with respect to X , Y , Z .

the laboratory frame. For instance, when the EFG changes direction during the NMR experiment because of molecular motions or sample spinning, the full information concerning relative orientations at different times is generally needed for analysis of spin dynamics and relaxation rates.

5.2 Hamiltonian

The nuclear quadrupolar Hamiltonian is introduced in *Internal Spin Interactions and Rotations in Solids* and in *Quadrupolar Interactions*. In the Cartesian coordinates of an arbitrary axes system, it is

$$\begin{aligned}\hat{\mathcal{H}}_Q = & \frac{eQ}{4I(2I-1)\hbar} \{V_{zz}[3\hat{I}_z^2 - I(I+1)] \\ & + (V_{xx} - V_{yy})(\hat{I}_x^2 - \hat{I}_y^2) + 2V_{xy}(\hat{I}_x\hat{I}_y + \hat{I}_y\hat{I}_x) \\ & + 2V_{xz}(\hat{I}_x\hat{I}_z + \hat{I}_z\hat{I}_x) + 2V_{yz}(\hat{I}_y\hat{I}_z + \hat{I}_z\hat{I}_y)\} \quad (28)\end{aligned}$$

This formula contains the tensor elements of $\mathbf{V}$, which depend on the orientation of the axes with respect to the PAS, as was pointed out above. Another representation of the Hamiltonian is in terms of irreducible tensor operators:

$$\hat{\mathcal{H}}_Q = \frac{1}{2\hbar} \sum_{k=-2}^2 (-1)^k \hat{Q}_k V_{-k} \quad (29)$$

where

$$\left. \begin{aligned}\hat{Q}_0 &= \frac{eQ}{2I(2I-1)} \frac{1}{\sqrt{6}} [\hat{I}_z^2 - I(I+1)] \\ \hat{Q}_{\pm 1} &= \mp \frac{eQ}{2I(2I-1)} (\hat{I}_z\hat{I}_{\pm} + \hat{I}_{\pm}\hat{I}_z) \\ \hat{Q}_{\pm 2} &= \frac{eQ}{2I(2I-1)} \hat{I}_{\pm}^2 \\ \hat{I}_{\pm} &= \hat{I}_x \pm i\hat{I}_y\end{aligned} \right\} \quad (30)$$

and

$$\left. \begin{aligned}V_0 &= \sqrt{\frac{3}{2}} V_{zz} \\ V_{\pm 1} &= \mp V_{xz} - iV_{yz} \\ V_{\pm 2} &= \frac{1}{2}(V_{xx} - V_{yy}) \pm iV_{xy}\end{aligned} \right\} \quad (31)$$

The transformation properties of the irreducible tensors make this form of the Hamiltonian particularly useful for description of rotations of the coordinate system. The notation of equation (29) is also helpful for writing out the Hamiltonian in matrix form.

5.3 Hamiltonian in Matrix Form

Since many aspects of the spin dynamics of quadrupolar nuclei can readily be explained by inspection of the structures of the matrices of the various contributions to the total Hamiltonian, we give here a few representative examples. The matrices are given in the standard representation of spin I , i.e., the matrix elements are $\langle m' | \hat{\mathcal{H}}_Q | m \rangle$, where $|m\rangle$ are the $2I + 1$

eigenstates of $\hat{I}_z$: $|I\rangle, |I-1\rangle, \dots, |-I+1\rangle, |-I\rangle$. The spin operator properties of the $\hat{Q}_k$ components in equation (29) place the coefficient V_0 in the diagonal elements, $V_{\pm 1}$ in elements one position removed from the diagonal, and $V_{\pm 2}$ two positions removed. As two examples, we give the matrices for $I = 1$,

$$\hat{\mathcal{H}}_Q = \frac{3eQ}{2I(2I-1)\hbar} \begin{pmatrix} \frac{1}{6}V_{zz} & \sqrt{\frac{1}{2}}V_{-1} & V_{-2} \\ -\sqrt{\frac{1}{2}}V_{+1} & -\frac{1}{3}V_{zz} & -\sqrt{\frac{1}{2}}V_{-1} \\ V_{+2} & \sqrt{\frac{1}{2}}V_{+1} & \frac{1}{6}V_{zz} \end{pmatrix} \quad (32)$$

and for $I = \frac{3}{2}$,

$$\begin{aligned}\hat{\mathcal{H}}_Q &= \frac{3eQ}{2I(2I-1)\hbar} \\ &\times \begin{pmatrix} \frac{1}{2}V_{zz} & \sqrt{\frac{1}{3}}V_{-1} & \sqrt{\frac{1}{3}}V_{-2} & 0 \\ -\sqrt{\frac{1}{3}}V_{+1} & -\frac{1}{2}V_{zz} & 0 & \sqrt{\frac{1}{3}}V_{-2} \\ \sqrt{\frac{1}{3}}V_{+2} & 0 & -\frac{1}{2}V_{zz} & -\sqrt{\frac{1}{3}}V_{-1} \\ 0 & \sqrt{\frac{1}{3}}V_{+2} & \sqrt{\frac{1}{3}}V_{+1} & \frac{1}{2}V_{zz} \end{pmatrix} \quad (33)\end{aligned}$$

In high-field NMR, the quadrupolar Hamiltonian is considered to be a perturbation of the Zeeman Hamiltonian $\hat{\mathcal{H}}_Z = \omega_0 \hat{I}_z$. The first-order perturbation is determined by the secular part of $\hat{\mathcal{H}}_Q$, i.e., the portion $\hat{\mathcal{H}}_Q^{(1)}$ of $\hat{\mathcal{H}}_Q$ that commutes with $\hat{\mathcal{H}}_Z$. Since the latter is represented by a diagonal matrix with nondegenerate eigenvalues, $\hat{\mathcal{H}}_Q^{(1)}$ retains only the diagonal elements of equations (32) and (33), ‘truncating’ $\hat{\mathcal{H}}_Q$ to

$$\hat{\mathcal{H}}_Q^{(1)} = \frac{1}{2} \Delta\omega_Q [\hat{I}_z^2 - \frac{1}{3}I(I+1)] \quad (34)$$

$\hat{\mathcal{H}}_Q^{(1)}$ determines the first-order energy level corrections $E_m^{(1)}$ given in equation (2). The second-order corrections $E_m^{(2)}$ of the eigenvalues involve double products of the off-diagonal elements of $\hat{\mathcal{H}}_Q$ divided by differences between Zeeman energies:

$$\begin{aligned}E_m^{(2)} = & -\frac{\omega_Q^2}{9\omega_0} m \left\{ 2[I(I+1) - 2m^2 - \frac{1}{4}] \left(\frac{|V_1|}{eq} \right)^2 \right. \\ & \left. - [I(I+1) - m^2 - \frac{1}{2}] \left(\frac{|V_2|}{eq} \right)^2 \right\} \quad (35)\end{aligned}$$

These eigenvalue equations are used to calculate first- and second-order quadrupolar shifts of transition frequencies. The expressions $(|V_1|/eq)^2$ and $(|V_2|/eq)^2$ in equation (35) are functions of the orientation of the Zeeman field with respect to the EFG principal axes and of η [see equations (31) and (22)–(27)]. For instance, the second-order shift of the central transition is

$$\begin{aligned}\Delta\omega_{-1/2 \leftrightarrow 1/2}^{(2)} = & -\frac{\omega_Q^2}{9\omega_0} [I(I+1) - \frac{3}{4}] \\ & \times \left[2 \left(\frac{|V_1|}{eq} \right)^2 - \left(\frac{|V_2|}{eq} \right)^2 \right] \quad (36)\end{aligned}$$

which for $\eta = 0$ reduces to

$$\Delta\omega_{-1/2 \leftrightarrow 1/2}^{(2)} = -\frac{\omega_Q^2}{16\omega_0} [I(I+1) - \frac{3}{4}] \times (1 - \cos^2 \theta)(9 \cos^2 \theta - 1) \quad (37)$$

The eigenfunctions of the Hamiltonian are also perturbed. In other words, the vectors representing them in wavefunction space are slightly tilted. The general formula for these tilted states is

$$|m\rangle \rightarrow |m\rangle + \sum_{m' \neq m} \frac{\langle m' | \hat{\mathcal{H}}_Q | m \rangle}{(m - m')\omega_0} |m'\rangle \quad (38)$$

which can be used to evaluate the Zeeman state mixing that determines the detectability of overtone spectra and the dipolar splittings in spectra of neighboring nuclei. The correction terms have the forms $(\omega_Q/\omega_0)(V_{\pm 1}/eq)|m \pm 1\rangle$ and $(\omega_Q/\omega_0)(V_{\pm 2}/eq)|m \pm 2\rangle$ multiplied by numerical coefficients. Because the corrections involve off-diagonal elements of $\hat{\mathcal{H}}_Q$ divided by ω_0 , they are considered to be second-order perturbations.

5.4 Density Matrix

The state of an ensemble of mutually noninteracting nuclei of spin I is described by a density matrix $\hat{\rho}$ having $2I + 1$ rows and columns. Since this is a Hermitian matrix, it has in addition to a unit-matrix term, $(2I + 1)^2 - 1$ independent traceless components (3 when $I = \frac{1}{2}$; 8 when $I = 1$; 15 when $I = \frac{3}{2}$; etc.). It is convenient to choose a basis set of mutually independent matrices or operators for the description of the density matrices. In the case of spin- $\frac{1}{2}$, the three operators $\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$ are the natural selection for that purpose, but for higher spin numbers the choices are not so obvious. A number of formalisms exist. Some are based on the use of irreducible tensor operators [i.e., variations of equation (30)].^{41,50,51} Others employ fictitious spin- $\frac{1}{2}$ operators^{21,52} or specially adapted operators.⁵⁴ Since the spin dynamics are determined by the Liouville–von Neumann equation

$$\frac{d\hat{\rho}}{dt} = i[\hat{\rho}, \hat{\mathcal{H}}] \quad (39)$$

the preferred formalism depends on the nature of the Hamiltonian to be analyzed, and is often the one that offers the simplest set of commutation relations. Not infrequently, however, other considerations such as ease of visualization, relaxation properties, or personal taste of the theoretician determine the choice of formalism.

Below, we give the traceless parts of the density matrices corresponding to the special spin states that were mentioned in Sections 2.3, 3.2, and 3.3. Rather than referring to a particular basis set, we reproduce here the full matrices in the standard representation. (Complete operator basis sets may be found

in the respective references.)^{21,41,52,53} For $I = 1$, we have mentioned Zeeman order $\hat{I}_z$ and quadrupolar order $\hat{Q}_z$,

$$\hat{I}_z = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{pmatrix}, \quad \hat{Q}_z = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & -2 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (40)$$

single quantum coherences $\hat{I}_x$ and $\hat{I}_y$ corresponding to x and y magnetization,

$$\hat{I}_x = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad \hat{I}_y = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 & -i & 0 \\ i & 0 & -i \\ 0 & i & 0 \end{pmatrix} \quad (41)$$

single quantum coherences $\hat{S}_x$ and $\hat{S}_y$ associated with selective excitation of the $(0, -1)$ transition,

$$\hat{S}_x = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}, \quad \hat{S}_y = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix} \quad (42)$$

and double quantum coherences with x and y phases,

$$\hat{D}_x = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix}, \quad \hat{D}_y = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix} \quad (43)$$

The $I = \frac{3}{2}$ spin states relevant to the discussions in this article are Zeeman order $\hat{I}_z$ and quadrupolar order $\hat{Q}_z$,

$$\hat{I}_z = \frac{1}{2} \begin{pmatrix} 3 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -3 \end{pmatrix}, \quad \hat{Q}_z = \frac{1}{2} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad (44)$$

three coherences associated with the central transition,

$$\hat{C}_x = \frac{1}{2} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad \hat{C}_y = \frac{1}{2} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & -i & 0 \\ 0 & i & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \quad (45)$$

$$\hat{C}_z = \frac{1}{2} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

and three coherences associated with the triple quantum transition,

$$\hat{T}_x = \frac{1}{2} \begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{pmatrix}, \quad \hat{T}_y = \frac{1}{2} \begin{pmatrix} 0 & 0 & 0 & -i \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ i & 0 & 0 & 0 \end{pmatrix} \quad (46)$$

$$\hat{T}_z = \frac{1}{2} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}$$

Note that $\hat{T}_z$ is equivalent to the ‘triple quantum order’ represented in Figure 5. The nonvanishing matrix elements in equations (42), (43), (45), and (46) form 2×2 submatrices. They are examples of fictitious spin- $\frac{1}{2}$ operators.

5.5 Hamiltonian in Rotating Frame

An rf field of amplitude ω_1 and carrier frequency ω is best described in the axis frame that rotates with frequency ω with respect to the laboratory frame. The corresponding rotating-frame Hamiltonian is

$$\hat{\mathcal{H}}_{\text{rf}} = \omega_1 \hat{I}_x \quad (47)$$

whose matrix elements are proportional to those of $\hat{I}_x$:

$$\langle m | \hat{I}_x | m \pm 1 \rangle = \frac{1}{2} \sqrt{I(I+1) - m(m \pm 1)} \quad (48)$$

In the same rotating frame, the Zeeman Hamiltonian is reduced to the resonance-offset Hamiltonian

$$\hat{\mathcal{H}}_{\text{os}} = (\omega_0 - \omega) \hat{I}_z = \Delta\omega_0 \hat{I}_z \quad (49)$$

The matrix elements of the quadrupolar Hamiltonian in the rotating frame are transformed to oscillating functions obtained by replacing V_k in equations (29), (32), and (33) with $V_k \exp(-ik\omega t)$. In the presence of rf fields, it is usually permissible to neglect the rapidly oscillating terms. This reduces $\hat{\mathcal{H}}_Q$ in the rotating frame to $\hat{\mathcal{H}}_Q^{(1)}$ of equation (34). In summary, we consider a rotating-frame Hamiltonian consisting of three terms:

$$\hat{\mathcal{H}}_R = \hat{\mathcal{H}}_Q^{(1)} + \hat{\mathcal{H}}_{\text{os}} + \hat{\mathcal{H}}_{\text{rf}} \quad (50)$$

In matrix form, it is for $I = 1$,

$$\hat{\mathcal{H}}_R = \frac{1}{2} \begin{pmatrix} \frac{1}{3}\Delta\omega_Q + 2\Delta\omega_0 & \omega_1\sqrt{2} & 0 \\ \omega_1\sqrt{2} & -\frac{2}{3}\Delta\omega_Q & \omega_1\sqrt{2} \\ 0 & \omega_1\sqrt{2} & \frac{1}{3}\Delta\omega_Q - 2\Delta\omega_0 \end{pmatrix} \quad (51)$$

and for $I = \frac{3}{2}$,

$$\hat{\mathcal{H}}_R = \frac{1}{2} \begin{pmatrix} \Delta\omega_Q + 3\Delta\omega_0 & \omega_1\sqrt{3} & 0 & 0 \\ \omega_1\sqrt{3} & -\Delta\omega_Q + \Delta\omega_0 & 2\omega_1 & 0 \\ 0 & 2\omega_1 & -\Delta\omega_Q - \Delta\omega_0 & \omega_1\sqrt{3} \\ 0 & 0 & \omega_1\sqrt{3} & \Delta\omega_Q - 3\Delta\omega_0 \end{pmatrix} \quad (52)$$

The corresponding matrices for higher values of I can be evaluated similarly. Here, we only mention that when m and $m \pm 1$ equal $-\frac{1}{2}$ and $\frac{1}{2}$, the square root in equation (48) reduces to $I + \frac{1}{2}$, resulting in

$$\langle -\frac{1}{2} | \hat{\mathcal{H}}_{\text{rf}} | \frac{1}{2} \rangle = \langle \frac{1}{2} | \hat{\mathcal{H}}_{\text{rf}} | -\frac{1}{2} \rangle = \frac{1}{2} \omega_1 (I + \frac{1}{2}) \quad (53)$$

The nutation frequencies of selective central transition nutation, equation (10), are determined by these matrix elements.

The various ways in which rf pulses affect a quadrupolar spin system were reviewed in Section 3. In an effort to keep that presentation succinct, a quantum mechanical explanation of the effects was not given. The following discussion is intended to show how the effects are related to the Hamiltonian in the rotating frame, equation (50). As in Section 3, we begin with an example of a nonquadrupolar spin to introduce the concepts of nutation, spin locking, and population transfer. Taking $I = \frac{1}{2}$ for simplicity, we have the Hamiltonian matrix

$$\hat{\mathcal{H}}_R = \frac{1}{2} \begin{pmatrix} \Delta\omega_0 & \omega_1 \\ \omega_1 & -\Delta\omega_0 \end{pmatrix} \quad (54)$$

If the rf field vanishes, the dependence of its eigenvalues on the offset is represented by two straight lines crossing at zero offset, as indicated by the broken lines in the top diagram of Figure 12. The associated eigenstates are $|\frac{1}{2}\rangle$ and $|\frac{1}{2}\rangle$. Introduction of the rf term changes the eigenvalues and eigenstates provided ω_1 [occupying the off-diagonal elements in equation (54)] is not much smaller than $\Delta\omega_0$ (the difference between the diagonal elements). This leads to an avoided level crossing in the eigenvalue diagram, with a residual level splitting of ω_1 at the center. This result follows immediately from the solution of the eigenvalue equation of the matrix of equation (54) with vanishing diagonal elements. When $\Delta\omega_0 = 0$, the eigenstates of $\hat{\mathcal{H}}_R$ are the linear combinations

$$|c+\rangle = (|\frac{1}{2}\rangle + |-\frac{1}{2}\rangle)/\sqrt{2} \quad (55)$$

$$|c-\rangle = (|\frac{1}{2}\rangle - |-\frac{1}{2}\rangle)/\sqrt{2} \quad (56)$$

Zeeman order corresponds to populations of the untitled $|\pm\frac{1}{2}\rangle$ wavefunctions. Since these are eigenstates of the Hamiltonian when $\Delta\omega_0 \gg \omega_1$, Zeeman order is spin locked far off resonance. Another way of expressing this is by saying that the density matrix $\hat{I}_z$, which represents Zeeman order, commutes with the Hamiltonian far off resonance. On resonance, the spin locked density matrix is $\hat{I}_x$, which corresponds to populations of the eigenstates $|c\pm\rangle$. Since $\hat{I}_z$ does not commute with the Hamiltonian on resonance, a spin system in thermal equilibrium is not spin locked on resonance, but rather undergoes nutation in the rf field with a frequency ω_{nut} equal to the level splitting, which in this case is ω_1 . Population transfer occurs when $\Delta\omega_0$ is swept slowly from above to below resonance. If the passage is sufficiently slow that the adiabatic condition of equation (7) is satisfied, an eigenstate of the Hamiltonian is changed into the state that is connected to it by continuity in the level diagram. The top diagram in Figure 12 shows that, when going from above to below resonance, the $|\frac{1}{2}\rangle$ state connects via $|c+\rangle$ to $|\frac{1}{2}\rangle$. (Compare the $z \rightarrow x \rightarrow -z$ trajectory of the magnetization vector in the axis system of Figure 7.) In this way, the density matrix is converted from $\hat{I}_z$ to $-\hat{I}_z$, and the populations of the Zeeman levels are exchanged.

These concepts are readily extended to quadrupolar spins. Examples of offset-dependent eigenvalues are plotted in the $I = 1$ and $I = \frac{3}{2}$ diagrams in Figure 12. They were calculated by numerical diagonalization of the matrices of equations (51) and (52) for selective rf excitation conditions ($\omega_1 < \Delta\omega_Q$). Avoided level crossings are indicated by the circles in the figure. They occur at values of $\Delta\omega_0$ for which two diagonal elements of the Hamiltonian are equal. The numbers above the circles mark the differences Δm of the m values of the crossing states. The residual level splittings are the nutation frequencies ω_{nut} of the corresponding excitations. For single quantum crossings ($\Delta m = 1$), they are determined by the respective off-diagonal elements in the Hamiltonian. For multiple quantum transitions, the residual splittings are to be calculated by higher-order perturbation theory, resulting in the general expression

$$\omega_{\text{nut}}(m' \leftrightarrow m) = M_{m' \leftrightarrow m} \omega_1 \left(\frac{\omega_1}{\Delta\omega_Q} \right)^{\Delta m - 1} \quad (57)$$

Figure 12 Eigenstate diagrams of a rotating frame Hamiltonian consisting of a first-order quadrupolar term, a frequency offset term, and an rf term. The eigenvalues are plotted versus the offset $\Delta\omega_0$. The $I = \frac{1}{2}$ diagram is representative of the case of a nonquadrupolar nucleus ($\Delta\omega_Q = 0$). The $I = 1$ and $I = \frac{3}{2}$ diagrams represent cases of weak irradiation ($\omega_1 < \Delta\omega_Q$). The actual $\Delta\omega_Q/\omega_1$ ratios used in the simulations were 5 and 10 for $I = 1$ and $\frac{3}{2}$, respectively. Eigenfunctions $|m\rangle$ outside the circled regions are indicated. The numbered circles mark regions of avoided level crossings and the respective values of Δm

Examples of the coefficients are, for $I = 1, M_{0 \leftrightarrow +1} = \sqrt{2}$, $M_{-1 \leftrightarrow +1} = 2$; for $I = \frac{3}{2}$, $M_{-\frac{1}{2} \leftrightarrow +\frac{1}{2}} = 2$, $M_{+\frac{1}{2} \leftrightarrow +\frac{3}{2}} = \sqrt{3}$, $M_{-\frac{1}{2} \leftrightarrow +\frac{3}{2}} = 2\sqrt{3}$, $M_{-\frac{3}{2} \leftrightarrow +\frac{3}{2}} = \frac{3}{2}$. Furthermore, $M_{m' \leftrightarrow m} = M_{m \leftrightarrow m'} = M_{-m' \leftrightarrow -m}$. The coefficients for $I = \frac{5}{2}$ are tabulated elsewhere.²³ The various excitation conditions listed in Figure 8 are easily located in Figure 12. Note that the double quantum transition of $I = \frac{3}{2}$ at $\Delta\omega_0 = \frac{1}{2}\Delta\omega_Q$ was omitted in Figure 8. In the areas outside the circles, i.e. when the irradiation is off-resonance, the eigenstates are essentially pure Zeeman states $|m\rangle$. The corresponding spin locked spin configurations are

Figure 13 Eigenstate diagrams of a rotating frame Hamiltonian consisting of a first-order quadrupole term, a frequency offset term, and an rf term. The eigenvalues are plotted versus the quadrupole splitting $\Delta\omega_Q$. The diagrams represent cases of small frequency offsets ($\Delta\omega_0 < \omega_1$). The actual $\Delta\omega_0/\omega_1$ ratios used in the simulations were 0.25 and 0.15 for $I = 1$ and $\frac{3}{2}$, respectively. The eigenvalue levels for vanishing $\Delta\omega_Q$ are equally spaced by ω_1 . The eigenfunctions are indicated for large $\Delta\omega_Q$. $|c\pm\rangle$ are linear combinations of $|\pm\frac{1}{2}\rangle$ (see text)

populated states $|m\rangle$ (see Figure 5), which are represented by diagonal density matrices (e.g., $\hat{I}_z$, $\hat{Q}_z$, $\hat{C}_z$, and $\hat{T}_z$). An adiabatic sweep of $\Delta\omega_0$ interchanges the diagonal matrix elements by population transfer at the avoided level crossings.

Finally, examples of the dependence of the eigenvalues on $\Delta\omega_Q$ are shown in Figure 13. They were calculated for a relatively small resonance offset ($\omega_1 > \Delta\omega_0$). The case of nonselective excitation [Figure 8(a) and (f)] is represented at the centers of the diagrams ($\Delta\omega_Q \ll \omega_1$), where adjacent levels are split by ω_1 . A nonselective pulse affects the entire spin system, with a nutation frequency $\omega_{\text{nut}} = \omega_1$. At large quadrupolar splittings ($\Delta\omega_Q \geq \omega_1$) all the ω_1 -containing off-diagonal elements of equations (51) and (52) are nonsecular, except the central transition elements of $I = \frac{3}{2}$, which connect essentially degenerate states. Thus, the nutation frequency for the central transition is $(I + \frac{1}{2})\omega_1$, even when the quadrupolar splitting is large. The spin locked states of a spin 1 are seen to be made up of populations of Zeeman states, which can be adiabatically transferred into each other by slow sweeping of $\Delta\omega_Q$ from positive to negative values, or vice versa. In the case of half-integer spins, the situation is slightly different.

The eigenstates associated with the central transition are now the sum and difference of the Zeeman states [equations (55) and (56)] population of these eigenstates corresponds to the density matrix $\hat{C}_x$. Figure 13 further shows that an adiabatic zero-crossing of $\Delta\omega_Q$ transfers the $|c\pm\rangle$ states to the $|\pm\frac{3}{2}\rangle$ states, i.e., it transfers $\hat{C}_x$ to $\hat{T}_z$.

1 INTRODUCTION

Among the 43 transition metal isotopes active in NMR, 32 have a quadrupole moment. Most of them also have paramagnetic states, which usually prevent the usual NMR observation of these nuclei in solution. All these drawbacks greatly reduce the potentialities of NMR of transition metals. Nevertheless, a large amount of data are available for some of them, and they are of prime interest for chemists.

The situation is more severe for the lanthanides, since most of them have only paramagnetic states. Some actinides have NMR potentialities, but only uranium has been observed in solution.

The quadrupole moments that condition the width of the resonances, the gyromagnetic ratios, and the natural abundances that determine the sensitivity of the experiments are the three factors that can lead from easy observation to unobservability of these nuclei. We can therefore classify transition metals according to their observability—which is generally related to the number of papers cited in the literature.

As the quadrupolar relaxation mechanism is almost the only efficient relaxation process, most transition metal nuclei are always decoupled from neighboring nuclei. Consequently, relatively few coupling constants are known. Most of those that are known are with isotopes having spin- $\frac{1}{2}$, which are often used for the measurement of these couplings. This situation usually prevents the observation of homonuclear coupling constants.

The NMR-active transition metal nuclei have been the subjects of reviews or books,^{1–7} and theoretical^{8,9} and spectroscopic methods¹⁰ for such nuclei have been discussed. See also *Inorganic Nuclei: Low Sensitivity Transition Metals; Organometallic Compounds*.

2 NUCLEI WITHOUT RESONANCE KNOWN IN SOLUTION

Three elements, namely, hafnium, iridium, and gold, have NMR-active isotopes, but their large electric quadrupole moments and low gyromagnetic ratios prevent signals from being observed. (²⁰¹Hg is the fourth of this series, but, since mercury also has a spin- $\frac{1}{2}$ isotope, which is easy to observe, the NMR of this element is well known.) Their nuclear spin properties may be found in *Nuclear Spin Properties and Notation*.

All these nuclei have been observed in the metallic form. A one-bond coupling constant of 200 Hz is known between gold and phosphorus in the solid state. ²⁰¹Hg has also been observed in K₂Hg(CN)₄ in the solid state.¹¹

At the present level of development of NMR, none of these nuclei seem to present any prospect for solution studies.

3 NUCLEI WITH LIMITED RESULTS IN SOLUTION

Some nuclei with large quadrupole moments (e.g., ¹⁸¹Ta, ¹⁸⁵Re, and ¹⁸⁷Re), low receptivities (e.g., ⁵³Cr, ⁶¹Ni, and ⁹¹Zr), or both (e.g., ⁶⁷Zn, ¹⁰⁵Pd, and ¹⁸⁹Os) are very difficult to observe, but in some cases of a high-symmetry environment, resonances have been detected that at least allow the determination of precise NMR parameters.

3.1 Chromium

The receptivity of ⁵³Cr is half that of ¹³C, but its relatively large quadrupole moment of $-0.150 \times 10^{-28} \text{ m}^2$ reduces its observability. Some reviews have appeared.^{1–7,12} Only a few resonances were known before the publication of two papers giving most of the interesting data.^{13,14}

3.1.1 Chemical Shifts

Only one isotope, ⁵³Cr with spin $-\frac{3}{2}$ and a natural abundance of 9.55%, is NMR-active. The Ξ value of the most used reference, K₂CrO₄ in D₂O, is 5 652 477 Hz. Cr(CO)₆ has also been used as a reference. The relation between the two scales is $\delta(\text{CrO}_4^{2-}) = \delta(\text{Cr(CO)}_6) - 1796.5 \text{ ppm}$.

The chemical shifts range between -1900 and $+700 \text{ ppm}$ for the Cr(0) and Cr(VI) oxidation states, which are the only diamagnetic species for this element.

The influence of the counterion associated with CrO₄²⁻ shows a shielding effect from Na⁺ to Cs⁺, with NH₄⁺ being intermediate. The shielding increases slightly with concentration. The solvent has a greater influence; for example, CH₃CN solutions are deshielded by about 17 ppm compared with D₂O solutions.

Chromium chemical shifts are also temperature-dependent. The observed range of this effect is between 0.1 ppm K^{-1} for Na₂CrO₄ to 1 ppm K^{-1} for Cr(CO)₆. A large isotopic shielding of -1.3 ppm is observed between solutions in H₂O and D₂O.

The resonances of Cr(VI), which appear between $+700$ and -10 ppm , are well separated from the Cr(0) oxidation state, which spans the range from -1600 to -1900 ppm . An inverse

halogen behavior has been noticed in the series CrO_3X^- (with $\text{X} = \text{F}, \text{Cl}, \text{Br}$).

Forty-six carbene complexes $(\text{CO})_5\text{CrL}$ [with $\text{L} = \text{C}(\text{X})(\text{Y})$] appear between -1490 and -1740 ppm, and four isonitrile complexes (with $\text{L} = \text{C}=\text{N}-\text{R}$) are found between -1730 and -1775 ppm. The evolution of these chemical shifts may be interpreted according to the donor-acceptor properties of the ligand for the same type of symmetry.

3.1.2 Coupling Constants

Only a few values are reported in the literature: $^1J(^{53}\text{Cr}, ^{17}\text{O}) = 10$ Hz in CrO_4^{2-} and $^1J(^{53}\text{Cr}, ^{31}\text{P}) = 153$ Hz in $\text{Cr}(\text{CO})_5\{(\text{MeO})_2\text{P}(\text{CH}_2)_2\text{P}(\text{OEt})_2\}$ and 105 Hz in $\text{Cr}(\text{PF}_3)_6$.

3.1.3 Relaxation and Linewidths

Linewidths are between 4 and 3500 Hz. For carbenes, it has been shown that the broader lines are associated with the more reactive molecules in photolytic reactions.

Few relaxation measurements have been reported. Values of T_1 are usually very short—below 1 ms. The longest is 37 ms for Na_2CrO_4 . The evolution of T_1 with temperature for K_2CrO_4 has been published.⁶

3.2 Nickel

It is not its quadrupole moment, which is acceptable ($0.162 \times 10^{-28} \text{ m}^2$) that leads to difficulties in the observation of this element, but rather the low natural abundance, 1.13%, of the only NMR-active isotope: ^{61}Ni with spin $-\frac{3}{2}$.^{1,2,4-6} Only relatively recently^{15,16} have some publications appeared describing the resonances of some tri- and tetracoordinate complexes of $\text{Ni}(\text{O})$.

3.2.1 Chemical Shifts

Two references are used, and the preferred one is $\text{Ni}(\text{CO})_4$, neat or dissolved in C_6D_6 or CD_2Cl_2 . The Ξ value of this reference is 8 936 050 Hz for the neat sample. The second reference is $\text{Ni}(\text{PMe}_3)_4$ in toluene- d_8 . The relation between the two scales, $\delta(\text{Ni}(\text{CO})_4) = \delta(\text{Ni}(\text{PMe}_3)_4) + 15.2$ ppm, is only approximate.

The chemical shifts lie between -930 and $+940$ ppm. The values for the tricoordinate complexes are not distinct from the tetracoordinate ones. Nickel bound to four phosphorus atoms absorbs between -930 and $+267$ ppm. Carbonyl derivatives $\text{Ni}(\text{CO})_3\text{PX}_3$ fall in a short range between -60 and 93 ppm. Theoretical discussion of these chemical shifts awaits more experimental results.

3.2.2 Coupling Constants

Surprisingly for a quadrupolar nucleus with such a large quadrupole moment, many values have been published. All the phosphines observed have $^1J(^{61}\text{Ni}, ^{31}\text{P})$ values between 252 and 161 Hz. Phosphites give larger values around 400 Hz. The highest values are observed with $\text{Ni}(\text{PCl}_3)_4$, 450 Hz, and $\text{Ni}(\text{PF}_3)_4$, 482 Hz. These couplings allow indirect detection of nickel resonances using inverse experiments.¹⁶

3.2.3 Relaxation and Linewidths

To the best of our knowledge, only one T_1 measurement has been reported, namely, one on a degassed sample of $\text{Ni}(\text{CO})_4$ at 25°C . The high value of 0.218 s is surprising for a quadrupolar nucleus, but the result agrees with the narrow line observed for this compound (4 Hz). The relaxation mechanism is purely quadrupolar, and usually leads to greater linewidths of between 20 and 90 Hz.

3.3 Zinc

Zinc has only one NMR-active isotope: ^{67}Zn , with a spin $+\frac{5}{2}$.^{1,2,4-6} Its low natural abundance (4.11%), its moderate quadrupole moment ($0.150 \times 10^{-28} \text{ m}^2$), and its low resonant frequency ($\Xi = 6\,256\,819$ Hz for $\text{Zn}(\text{NO}_3)_2$ in H_2O) lead to poor observability. This situation has been overcome by the use of enriched samples.

3.3.1 Chemical Shifts

Since the solvent and temperature effects on the resonance of zinc in $\text{Zn}(\text{NO}_3)_2$, $\text{Zn}(\text{ClO}_4)_2$, and ZnSO_4 in H_2O are below 2 ppm, these salts have been used as reference samples. After the first observation around 1970, publications with some chemical interest appeared with the advent of pulse NMR spectrometers and high-field instruments. About 20 resonances have been observed under different conditions.

The most interesting features are the well-separated regions for the tetra- and hexacoordinated cations. The first fall in the range from 200 to 420 ppm, the second in the range from -35 to 100 ppm. Only ZnCl_2 and ZnBr_2 in H_2O seem to be exceptions to this rule. Because of chemical exchange, salts with anions other than NO_3^- , ClO_4^- , and SO_4^{2-} are very sensitive to concentration, with temperature dependences of about 0.48 ppm K^{-1} for ZnCl_2 and 0.61 ppm K^{-1} for ZnBr_2 . The large isotope effect of +13 ppm for ZnBr_2 when H_2O is replaced by D_2O has the same origin. Perchlorate solutions do not show an isotope effect.

Zinc NMR has been used to follow the complexation of this element by different ligands, some of them being biological molecules.

Some theoretical studies are able to predict the trend of the different observed chemical shifts.¹⁷ No coupling constants have been observed with this nucleus.

3.3.2 Relaxation and Linewidths

The linewidths of zinc resonances have often been used in the study of complexation of zinc salts by different ligands or different biological molecules. Usually they are found between 20 and 1500 Hz, but linewidths of the order of 6000 Hz have been observed in biological complexes.

Relaxation measurements usually give $T_1 = T_2$, but the complex formed with insulin gives $T_2 < T_1$, which is explained by the conditions of non-extreme narrowing.

Zinc NMR seems to be very difficult and not very promising.

3.4 Zirconium

The only active isotope of this element, ^{91}Zr with spin $-\frac{5}{2}$ has a receptivity six times greater than ^{13}C . However, it has

not yet been the subject of much active research.^{2,4-6,15} Its moderate quadrupole moment of $-0.206 \times 10^{-28} \text{ m}^2$, which is similar to that of ^{59}Co , is not a major difficulty. It is therefore surprising that little work has been done on this nucleus.

3.4.1 Chemical Shifts

The reference sample is $(\text{C}_5\text{H}_5)_2\text{ZrBr}_2$, which has the narrowest resonance. The Ξ value is 9 296 300 Hz, but this frequency seems to be dependent on the experimental conditions: solvent, concentration, temperature, and counterions. A temperature effect of 0.5 ppm K^{-1} has been observed on $(\text{PhCMe}_2\text{CH}_2)_4\text{Zr}$, but the chemical shift of $\text{Cp}_2\text{Zr}(\text{CH}_3)[\text{HC}(\text{SO}_2\text{CF}_3)_2]$ remains constant between 25 and 80°C .

The chemical shifts range between -390 and $+900 \text{ ppm}$, but recently a high deshielding effect has been observed for $(\text{PhCMe}_2\text{CH}_2)_4\text{Zr}$, which appears around $+2675 \text{ ppm}$.^{17,18} Most of the observed compounds are dicyclopentadienyl derivatives, for which an inverse halogen dependence has been observed, as for all the elements of this column of the Periodic Table having a d^0 structure: the behavior of chemical shifts has been tentatively explained by the HOMO-LUMO concept, and crude additivity rules have been suggested.¹⁵

3.4.2 Coupling Constants

Only a few coupling constants are known. $^1J(^{91}\text{Zr}, ^{13}\text{C}) = 81.5 \text{ Hz}$ was measured on a ^{13}C -enriched $\text{Zr}(\text{CO})_6^{2-}$ -sample. The results from an interesting experiment are shown in Figure 1. These allowed the measurement of $^1J(^{91}\text{Zr}, ^{11}\text{B}) = 18 \text{ Hz}$ and $\frac{1}{4}[3 ^1J(^{91}\text{Zr}, ^1\text{H}) + ^3J(^{91}\text{Zr}, ^1\text{H})] = 28 \text{ Hz}$ which

Figure 1 (a) ^{91}Zr NMR spectrum. (b) ^{11}B -decoupled. (c) ^1H -decoupled. (d) ^1H - and ^{11}B -decoupled. (Reproduced by permission of the American Chemical Society from B. G. Sayer, J. I. A. Thompson, N. Hao, T. Birchall, D. R. Eaton, and M. J. McGlinchey, *Inorg. Chem.*, 1981, 20, 3748)

leads to $^1J(^{91}\text{Zr}, ^1\text{H}) = 37 \text{ Hz}$ if the three-bond coupling constant is assumed to be negligible.

3.4.3 Relaxation and Linewidths

Only two relaxation time measurements have been performed. The earliest (1957) on $\text{ZrF}_6(\text{NH}_4)_2$ gave $T_1 = 0.001 \text{ s}$; the most recent one on Cp_2ZrBr_2 gives 0.017 s . The linewidths range between 20 Hz for the reference to 7000 Hz for Cp_2Zr diene complexes. These linewidths may sometimes be reduced by proton decoupling, as for $(t\text{-Bu})_4\text{Zr}$, where $\Delta\nu_{1/2}$ decreases from 45 Hz (normal) to 20 Hz (decoupled). A decrease in the linewidth has been observed for $\text{Cp}_2\text{Zr}(\text{CH}_3)[\text{HC}(\text{SO}_2\text{CF}_3)_2]$, where $\Delta\nu_{1/2} = 7000 \text{ Hz}$ at 25°C and 2800 Hz at 80°C .

This nucleus seems to be promising, with the development of high-field instruments.

3.5 Palladium

^{105}Pd is the only NMR-active isotope of this element, with a natural abundance of 22.2% and a spin of $-\frac{5}{2}$. It has a large quadrupole moment of $0.660 \times 10^{-28} \text{ m}^2$, which has made observation almost impossible. Its receptivity is higher than that of ^{13}C . Nevertheless, one resonance has been observed for PdCl_6^{2-} in solution.^{2,19} The Ξ value is 4 586 100 Hz and is solvent dependent, as is the linewidth which is between 1 200 and 25 000 Hz.

3.6 Tantalum

With a natural abundance of 99.9%, ^{181}Ta , with spin $+\frac{7}{2}$, is one of the most receptive nuclei.⁴⁻⁶ But its extremely large quadrupole moment of $3.170 \times 10^{-28} \text{ m}^2$ leads almost to unobservability. It was first observed in TaF_6^- in HF/HNO_3 solution,¹ then in KTaCl_6 in CH_3CN ,² from which the Ξ value of 11 989 600 Hz has been determined, the linewidth of the resonance being 4400 Hz.

In 1986, three compounds were observed:²⁰ $(\text{Et}_4\text{N})(\text{TaCl}_6)$ in a $\text{CH}_3\text{CN}/(\text{CH}_3)_2\text{CO}$ 1/1 mixture and used as reference with a linewidth of 4300 Hz, $\text{K}_2(\text{TaF}_7)$ in 48% HF , which appears at -2295 ppm with $\Delta\nu_{1/2} = 28 700 \text{ Hz}$, and $(\text{Et}_4\text{N})[\text{Ta}(\text{CO})_6]$ in $\text{THF}/\text{CH}_3\text{CN}$ 5/1, found at -3450 ppm and with a linewidth of 6700 Hz. The behavior seems to parallel that of ^{93}Nb and ^{183}W . The linewidth of TaF_6^- is reduced by a factor 6 from 0°C to 80°C .

3.7 Rhenium

This element has two active isotopes in NMR: ^{185}Re and ^{187}Re , both with spin $+\frac{5}{2}$. Their natural abundances are 37.5% and 62.5%, respectively. They have about the same resonant frequency. Consequently, ^{187}Re has a receptivity that is about twice that of ^{185}Re , and is the preferred isotope to observe. They also have similar quadrupole moments: $2.180 \times 10^{-28} \text{ m}^2$ for the first and $2.070 \times 10^{-28} \text{ m}^2$ for the second. Except for ^{181}Ta and ^{235}U , they have the largest quadrupole moments of all stable isotopes. This situation leads to a very difficult observability, which explains the scarcity of publications devoted to this element.^{1,2,4-6}

Figure 2 8 MHz $^{185/187}\text{Re}$ NMR spectrum of $[(\text{C}_2\text{H}_5)_4\text{N}][\text{ReS}_4]$ in $\text{MeCN}/\text{CH}_2\text{Cl}_2/\text{Me}_2\text{SO}$ at 305 K. (Reproduced by permission of Schweizerischen Chemiker-Verbandes from A. Müller, E. Krickemeyer, H. Bögge, M. Penk, and D. Rehder, *Chimia*, 1986, **40**, 50)

The adopted reference is ReO_4^- for which the Ξ values are $\Xi(^{185}\text{Re}) = 22\,524\,600\text{ Hz}$ and $\Xi(^{187}\text{Re}) = 22\,751\,600\text{ Hz}$. As the frequencies are very near and the chemical shift ranges of the transition metal nuclei are large, the two isotopes are often observed in the same spectrum (see Figure 2). The difference between the two resonances is about 10 000 ppm. The only reported chemical shifts are for $\text{Re}(\text{CO})_6\text{Cl}\cdot\text{HCl}$ in CH_3CN (-3400 ppm , $\Delta\nu_{1/2} = 2.4\text{ kHz}$) and Et_4NReS_4 in $\text{CH}_3\text{CN}/\text{CH}_2\text{Cl}_2/(\text{CH}_3)_2\text{SO}$ ($+3400\text{ ppm}$, $\Delta\nu_{1/2} = 1.96\text{ kHz}$). These shifts are comparable to those of Mo and V.

The relaxation of ^{187}Re in ReO_4^- has been studied as a function of temperature.

Surprisingly, several coupling constants have been measured indirectly using ^1H , ^{13}C , and ^{31}P relaxation techniques: $^1J(^{187}\text{Re}, ^{31}\text{P}) = 1260\text{ Hz}$ and $^1J(^{187}\text{Re}, ^1\text{H}) = 440\text{ Hz}$ in $\text{HRe}(\text{CO})_4\text{PPh}_3$, $^1J(^{187}\text{Re}, ^1\text{H}) = 385\text{ Hz}$ in $\text{HRe}(\text{CO})_5$, and $^1J(^{187}\text{Re}, ^{13}\text{C}) = 360\text{ Hz}$ and 397 Hz for two carbonyls in $[\text{Re}_3(\mu\text{-H})_4(\text{CO})_{10}]^-$. The future prospects for spectroscopy of this element are not encouraging.

3.8 Osmium

One of the isotopes, ^{187}Os , has spin $+\frac{1}{2}$ and has the lowest receptivity of all nuclei. The other NMR-active isotope is ^{189}Os , with spin $+\frac{3}{2}$. Its natural abundance of 16.1% leads to a receptivity that is twice that of ^{13}C , but its very large quadrupole moment of $0.856 \times 10^{-28}\text{ m}^2$ is a large obstacle to its observation. Consequently, the observation of ^{189}Os has been limited to OsO_4 , molten or dissolved in CCl_4 , where the Ξ value is $7\,765\,400\text{ Hz}$. The observed linewidth on this compound is 860 Hz .²

Relaxation measurements on ^{189}Os have been performed on OsO_4 in CCl_4 , for which $T_1 = 370\text{ }\mu\text{s}$, and have been used to compare the quadrupole moment of ^{189}Os with those of ^{99}Ru and ^{101}Ru .

4 NUCLEI WITH SOME POTENTIALITIES

4.1 Scandium

The only stable isotope of scandium, ^{45}Sc , has spin $+\frac{7}{2}$ and a high receptivity, equal to 0.3 that of the proton. This is a nucleus that is easy to observe. Its quadrupole moment of $-0.220 \times 10^{-28}\text{ m}^2$ is not too large, and facilitates

the observation of scandium. The limited number of papers in the literature arises mainly from the chemistry of this element being essentially limited to ionic forms studied in solution.^{1,2,4-6}

4.1.1 Chemical Shifts

The reference is $\text{Sc}(\text{ClO}_4)_3$, 0.1 M at low pH in water. The observed resonance is in fact $\text{Sc}(\text{H}_2\text{O})_6^{3+}$ which has a Ξ value of $24\,291\,700\text{ Hz}$. Depending on the counterion associated with Sc^{3+} in H_2O and on the concentration, the observed shifts range from -88 to $+27\text{ ppm}$. These variations reflect the equilibrium between the counteranion and the water molecules. Exchange studies have also been performed using temperature and pressure variations. The exchange effect leads to a large isotopic effect of -6.2 ppm between H_2O and D_2O , which may be of reverse sign ($+1\text{ ppm}$) in 10 M NaOH solutions.

Some complex ions enlarge the chemical shift range from $+288\text{ ppm}$ for ScBr_6^{3-} to -115 ppm for $\text{Sc}(\text{OH})_4^-$. Sc NMR has been used to identify the following species in solution: $[\text{ScCl}_{6-x-y}(\text{SCN})_x(\text{CH}_3\text{CN})_y]^{3-y}$ and $\text{ScCl}_{6-n}[\text{OP}(\text{OR})_3]_n^{3-n}$.

4.1.2 Coupling Constants

Some coupling constants are known with fluorine, $^1J(^{45}\text{Sc}, ^{19}\text{F}) = 180\text{ Hz}$ in ScF_6^{3-} , with phosphorus, $^2J(^{45}\text{Sc}, ^{31}\text{P}) = 30\text{--}40\text{ Hz}$ in $\text{ScCl}_{6-n}[\text{OP}(\text{PMe})_3]_n^{3-n}$, and with boron, $^1J(^{47}\text{Sc}, ^{11}\text{B}) = 15.5\text{ Hz}$, and proton, $^2J(^{45}\text{Sc}, ^1\text{H}) = 30\text{ Hz}$, both in $\text{Sc}(\text{BH}_4)_3$.

4.1.3 Relaxation and Linewidths

The linewidths range from 29 Hz , corresponding to $T_1 = 7.2\text{ ms}$, to 4550 Hz . The evolution of the linewidths with concentration or with the addition of other counterions has been used to probe the existence of labile complexes or contact ion pairs.

4.2 Titanium

The two isotopes, ^{47}Ti with spin $-\frac{5}{2}$, and ^{49}Ti , with spin $-\frac{7}{2}$, have resonant frequencies differing only by 267 ppm , ^{49}Ti being at higher frequency.^{1,2,4-6,15} The resonances of both isotopes always appear in all spectra. When different species are present, to avoid the overlapping between the two isotope resonances, it has been suggested recently that a $140\text{ }\mu\text{s}$ delay before the acquisition be used, such that the resonances of ^{47}Ti decrease completely.²¹

Both isotopes have a moderate quadrupole moment: $0.290 \times 10^{-28}\text{ m}^2$ for ^{47}Ti and $0.240 \times 10^{-28}\text{ m}^2$ for ^{49}Ti , so that the higher frequencies have the narrower linewidths.

4.2.1 Chemical Shifts

The reference is TiCl_4 neat and its resonances seems independent of the solvent. The Ξ values are $5\,637\,583\text{ Hz}$ for ^{47}Ti and $5\,639\,091\text{ Hz}$ for ^{49}Ti ; their linewidths are around $6\text{--}8\text{ Hz}$.

The hexacarbonyl complex $\text{Ti}(\text{CO})_6^{2-}$ is the most shielded derivative, and is found at -1389 ppm . On the opposite

side, TiI_4 is observed at +1278 ppm. Titanium has an inverse halogen dependence, as does zirconium, and this behavior has recently been explained theoretically.²² The NMR applications of this element have begun to increase, and have been used to distinguish between enantiomers and to prove the existence of complexes with aromatic compounds, electron donor–acceptor ligands, and with small peptides. It has been found that the alkoxides Ti(OR)_4 are difficult to observe, probably because of the presence of polymeric structures.

4.2.2 Coupling Constants

Only two coupling constants have been observed: $^1J(^{49}\text{Ti}, ^{13}\text{C}) = 23 \text{ Hz}$ and $^1J(^{49}\text{Ti}, ^{19}\text{F}) = 34 \text{ Hz}$.

4.2.3 Relaxation and Linewidths

According to their quadrupole moments, the linewidths of ^{47}Ti are about 1.5 times larger than those of ^{49}Ti . The spin–lattice relaxation time has been measured for both isotopes for TiF_6^{2-} and TiCl_4 at different concentrations in *n*-pentane and at different temperatures in toluene. The values for ^{49}Ti are about 0.1 s.

4.3 Manganese

The only stable isotope ^{55}Mn of this element has spin $+\frac{5}{2}$, a high receptivity, 1000 times that of ^{13}C , but a large quadrupole moment of $0.330 \times 10^{-28} \text{ m}^2$, which considerably reduces the observability of the manganese resonances.^{1,2,4,5} On the other hand, the only diamagnetic states correspond to the +1, 0, –1 oxidation states, which do not comprise the major part of the chemistry of this element. An exception to this rule is MnO_4^{2-} .

4.3.1 Chemical Shifts

These are all referred to $\text{KMnO}_4/\text{H}_2\text{O}$ solution, where the Ξ value is 24 789 060 Hz. This resonance depends on concentration, solvent (18 ppm from H_2O to hexamethylphosphoramide), and temperature (0.3 ppm K^{-1}). An isotope effect of –0.76 ppm is reported between H_2O and D_2O solutions. MnO_4^- is the only observed Mn(VII) oxidation state; all other molecules are mainly carbonyl or nitroxyl derivatives. The total chemical shift range is from +20 ppm (MnO_4^-) to –2953 ppm [$\text{MnH}(\text{PF}_3)_5$]. The +1 oxidation state is roughly between –1000 and –1500 ppm and the –1 oxidation state between –1700 and –3000 ppm. Several interesting correlations have been more or less established between the chemical shifts and the mean excitation energy ΔE , the σ -donor properties in the LMn(CO)_5 series, the Mössbauer isomer shifts for the $\text{R}_{3-n}\text{X}_n\text{–Mn(CO)}_5$ species, the rate of demetalation, and the ^{17}O chemical shifts.

Theoretical studies agree with the experimental results on model molecules⁹ and the sensitivity of the chemical shifts is such that it allows the determination of the relative concentration of inseparable isomers in solution. High-pressure experiments up to $3 \times 10^7 \text{ Pa}$ at different temperatures have been performed to study the equilibrium during the hydrogenation of $\text{Mn}_2(\text{CO})_{10}$.

4.3.2 Coupling Constants

Most of the known coupling constants are those with phosphorus in $\text{Mn(CO)}_5\text{L}$ derivatives. The values range between 140 and 405 Hz, the coupling constants to phosphites being larger than those to phosphines. Values of $^1J(^{55}\text{Mn}, ^{13}\text{C})$ ranging from 111 to 121 Hz have been observed in Mn(CNR)_6^+ , and MnO_4^- gives rise to a $^1J(^{55}\text{Mn}, ^{17}\text{O}) = 30 \text{ Hz}$.

4.3.3 Relaxation and Linewidths

The longitudinal relaxation time is 0.84 s in MnO_4^- . This result corresponds to a linewidth of 3.5 Hz. This seems to be the only T_1 measurement.

With some exceptions, the reported linewidths are found between 1000 and 21 500 Hz. They have been used to measure the exchange rate of electrons between diamagnetic and paramagnetic states. The two species $\text{Mn}[\text{CNC}(\text{CH}_3)_3]_6^{+/2+}$ and $\text{Mn}(\text{CNC}_6\text{H}_{11})_6^{+/2+} \text{BF}_4^-$ were observed under pressures up to 20 MPa and at different temperature in many solvents. The thermodynamic parameters of the exchange were determined.

Despite its high receptivity, the use of ^{55}Mn NMR is greatly handicapped by the large ^{55}Mn quadrupole moment.

4.4 Copper

The two stable isotopes of this element have spin $+\frac{3}{2}$, with a natural abundance of 69.1% for ^{63}Cu and 30.9% for ^{65}Cu .^{1–6} As they have similar resonant frequencies and similar quadrupole moments ($-0.220 \times 10^{-28} \text{ m}^2$ for ^{63}Cu and $-0.204 \times 10^{-28} \text{ m}^2$ for ^{65}Cu), ^{65}Cu is preferred, since it has a larger receptivity. A disadvantage is that the copper resonance from the probe is also observed at about 2000 ppm as a broad band with a linewidth between 7 and 14 kHz. When the observed resonances have smaller linewidth, this artifact may be suppressed using a delay before the acquisition, or by using an echo experiment. Note that Na^+ is found at –2400 ppm from the ^{63}Cu resonances.

4.4.1 Chemical Shifts

Only the Cu(I) oxidation state is observed in complexes having a high symmetry. The usual reference is $\text{Cu}(\text{MeCN})_4^+$ in CH_3CN solution. The Ξ values are 26 515 441 Hz for ^{63}Cu and 28 403 658 Hz for ^{65}Cu . The resonances do not depend on the usual counterions. Most complexes are found between 550 and –434 ppm. Resonances of carbonyl clusters are observed at very low frequencies around –2410 ppm, as for cobalt clusters. The relative small chemical shift range arises from the d^{10} structure of these molecules.

As the complexes are strongly bonded to copper, they protect the nucleus from external perturbations. Consequently, the chemical shifts of copper in these complexes are not sensitive to the concentration, or to the nature of the solvent and of the counterions. Large effects do arise if there is chemical exchange. The temperature effect on the shifts is relatively small, ranging between –0.055 and –0.75 ppm K^{-1} . Contrary to some early observations, copper follows the normal halogen effect. This behavior has been the subject of some theoretical investigations.¹⁷

Copper resonances in complexes with phosphine ligands are observed at lower frequencies (90–70 ppm) than those with phosphites (250–150 ppm). Complexes with different ligands have copper resonances that fall between these ranges, but are often not observed since the disymmetry considerably broadens the lines.

4.4.2 Coupling Constants

Only a few coupling constants are known. Most are one-bond coupling constants between ^{63}Cu and ^{31}P , which range between 1100 and 1460 Hz. A lower value has been observed at 790 Hz. These couplings have been used to observe copper indirectly by MINDOR (modified internuclear double resonance) or TINDOR (transferred internuclear double resonance) techniques.⁶

Only one $^1J(^{63}\text{Cu}, ^{13}\text{C})$ of 800 Hz has been measured on a ^{13}C -enriched sample of $[\text{Cu}(\text{CO})(\text{O}-t\text{-Bu})]_4$.

4.4.3 Relaxation and Linewidths

The quadrupolar mechanism is always dominant. Linewidths range from 20 to 28 000 Hz. Rapid chemical exchange may also increase the widths. The lower linewidths are found in clusters, as for cobalt.

The linewidths are sensitive to solvent, temperature, and concentration, and these properties have been used to study ligand exchange. A special case is the exchange between Cu(I) and the paramagnetic Cu(II) species. Here, the linewidth of Cu(I) is a function of the exchange rate.

4.5 Niobium

The only stable isotope of this element, ^{93}Nb , with spin $+\frac{9}{2}$, has one of the highest receptivities: about half that of the proton, but its relatively large quadrupole moment of $-0.320 \times 10^{-28} \text{ m}^2$ seriously limits its observability.^{1–6}

4.5.1 Chemical Shifts

A reference has not been definitively chosen. The most used is NbCl_6^- in CH_3CN for which $\Xi = 24\,476\,193 \text{ Hz}$, but NbF_6^- or NbOCl_3 have also been proposed. The latter one is equivalent to VOCl_3 , used as reference for vanadium, which would allow direct comparison between these two nuclei. Its drawback is its large linewidth of 700 Hz compared with the narrow band observed with the solution of $\text{NbCl}_5 + \text{Et}_4\text{Cl}$ in *dry* CH_3CN . We shall use this last reference in this article. The relations with the two most used scales are $\delta(\text{NbCl}_6^-) \approx \delta(\text{NbOCl}_3) - 460 \text{ ppm}$ and $\delta(\text{NbCl}_6^-) \approx \delta(\text{NbF}_6^-) - 1500 \text{ ppm}$. These conversion factors are not unique, since the measured values depend on the nature of the observed species, which are not always clearly identified.

The observed chemical shift range has been extended by about +2500 ppm,²³ and is now between +2600 and –4800 ppm. Niobium chemical shifts often parallel those of vanadium.⁷ The Nb(V) oxidation state has a d^0 structure, and is not very sensitive to solvent, concentration, or temperature effects. Niobium NMR has been used to study the mixture of species $\text{NbEX}_{4-n}\text{Y}_n$, with $\text{E} = \text{O}, \text{S}, \text{Se}, \text{Te}$. The identification

of species is sometimes based on a pairwise additivity rule. Deviations from this rule seem to be related to the preparation of the samples. A theoretical study has improved the understanding of the origin of the chemical shifts in these series, which is related to d–d transitions.^{9,24}

Low-valent Nb(I) and Nb(–I) , in contrast, have d electrons and are very sensitive to medium and temperature effects: 0.18 ppm K^{-1} for Nb(CO)_6 and 0.40 ppm K^{-1} for CpNb(CO)_4 . Large isotopic effects are observed: –6 ppm for H/D substitution for CpNb(CO)_3 and 0.173 ppm for $^{12}\text{C}/^{13}\text{C}$ exchange for Nb(CO)_6^- . Low-valent niobium complexes usually appear at lower frequencies.

4.5.2 Coupling Constants

Only a few coupling constants are known. $^1J(^{93}\text{Nb}, ^1\text{H})$ ranges between 36 and 80 Hz in hydrides, and 281 Hz $< ^1J(^{95}\text{Nb}, ^{19}\text{F}) < 410 \text{ Hz}$ and $^2J(^{95}\text{Nb}, ^{19}\text{F}) = 53 \text{ Hz}$ in $\text{Nb(PF}_3)_6^-$ where $^1J(^{95}\text{Nb}, ^{31}\text{P}) = 1050 \text{ Hz}$. Coupling constants with ^{13}C are known only for CpNb(CO)_4 : $^1J(^{95}\text{Nb}, ^{13}\text{C}) (\text{CO}) = 236 \text{ Hz}$ and $^1J(^{95}\text{Nb}, ^{13}\text{C}) (\text{Cp}) = 13 \text{ Hz}$. A one-bond coupling constant of $\pm 10 \text{ Hz}$ between Nb and ^{11}B has been observed.

4.5.3 Relaxation and Linewidths

The dominant relaxation mechanism is quadrupolar. The linewidths range from a few to 13 000 Hz. As is usual for quadrupolar nuclei, the linewidths have been used for the identification of species on the basis of their symmetry. The relaxation has been studied between 270 and 320 K in NbOF_5^{2-} in CH_3CN , and used for microdynamical studies.

4.6 Technetium

^{99}Tc is the most stable isotope of this element, having spin $+\frac{9}{2}$ and a quadrupole moment of $-0.129 \times 10^{-28} \text{ m}^2$.^{1,2,4,6} The observation of this radioactive element requires special equipment for handling the samples, and for security during the measurements. As it is artificially produced, its abundance is always 100%. It is the fifth most sensitive nucleus. A test has shown²⁴ that a 10^{-7} M solution of TcO_4^- gives a reasonable signal-to-noise ratio after 12 h of data accumulation on a 250 MHz (^1H) spectrometer. Despite its radioactivity, the literature on ^{99}Tc is rapidly growing, since it is used for structural studies of complexes used in diagnostic nuclear medicine.

4.6.1 Chemical Shifts

The reference is NH_4TcO_4 for which $\Xi = 22\,508\,314 \text{ Hz}$ in D_2O . It seems that no detailed studies on the effects of solvent, concentration, and temperature have been reported, but according to its d^0 electronic structure, it may be anticipated that these effects are small. Except for Tc(0) , the chemical shift ranges of the different oxidation states are more or less distinct. Tc(VII) derivatives are found between +396 and 0 ppm. Tc(V) compounds lead to the largest range, between +5500 and +806 ppm, with the exception of TcH_9^{2-} (observed at –3672 ppm). Tc(III) compounds are between

−78 and −1329 ppm, Tc(I) compounds between −1460 and −3517 ppm, and the ditechneum carbonyls between −2477 and −2600 ppm. The total range is therefore about 9200 ppm. Theoretical interpretations have been published.⁹

4.6.2 Coupling Constants

TcH₉^{2−} provides the only example of a ¹J(⁹⁹Tc, ¹H) coupling constant, which has a value of 24 Hz. Three different ¹J(⁹⁹Tc, ¹⁷O) values are known: 139.8, 131.6, and 87 Hz. Only one coupling constant with fluorine has been observed, with a value of 259 Hz. As usual, several ¹J(⁹⁹Tc, ³¹P) values have been reported, with values between 400 and 1750 Hz, and even a two-bond phosphorus–technetium coupling constant of 40 Hz has been observed.

4.6.3 Relaxation and Linewidths

Some *T*₁ and *T*₂ measurements have been performed. A *T*₂ value of 0.4 s observed for Tc₂(CO)₁₀ corresponds to the smallest linewidth of 1.4 Hz. More usually, broad bands are obtained, with Δ*ν*_{1/2} > 1000 Hz, the largest one observed, for TcOCl₄[−], being about 20 000 Hz.

4.7 Ruthenium

This element has two active isotopes, ⁹⁹Ru and ¹⁰¹Ru, both with spin $\frac{5}{2}$.^{1–6} They have about the same natural abundance (12.7% for ⁹⁹Ru and 17% for ¹⁰¹Ru), but they have large and different quadrupole moments: 0.079 × 10^{−28} and 0.457 × 10^{−28} m², respectively. ⁹⁹Ru has the same receptivity as ¹³C, and that of ¹⁰¹Ru is about twice that of ⁹⁹Ru. Nevertheless, it is ⁹⁹Ru that is usually observed, since its low quadrupole moment leads to sharper lines.

Although ⁹⁹Ru seems a good quadrupolar nucleus, it was, in fact, observed in solution only in 1981, by two independent groups. Since then, few studies have been published. The main difficulty arises from acoustic ringing, since the observation frequencies are relatively low.

Only Ru(0), Ru(II), and Ru(III) oxidation states are suitable for solution studies.

4.7.1 Chemical Shifts

The reference is K₄Ru(CN)₆ in D₂O, for which Ξ(⁹⁹Ru) = 4 605 152 Hz and Ξ(¹⁰¹Ru) = 5 161 369 Hz. The drawback of this reference is its large temperature dependence of 0.7 ppm K^{−1}. It should be noted that ³⁹K⁺ appears at +13 360 ppm from the reference.

The chemical shifts range from −1270 ppm for ruthenocene to +16 050 ppm for Ru(H₂O)₆²⁺. These shifts are very sensitive to the chemical environment, and have been used to identify different stereoisomers. Consequently, they are dependent on concentration, counterions, and solvents, and there is a temperature coefficient of up to 1 ppm K^{−1}. A theoretical study of the chemical shifts⁹ has been published, but more experiments are needed to find some rules to interpret their evolution.

4.7.2 Coupling Constants

Only three coupling constants are known in solution: ¹J(⁹⁹Ru, ¹⁷O) = 23.4 Hz in RuO₄, ¹J(⁹⁹Ru, ¹³C) = 44.1 Hz in Ru(CN)₆^{4−}, and ¹J(⁹⁹Ru, ¹¹⁹Sn) = 843 Hz in [Ru(SnCl₃)₅Cl]^{4−}.

4.7.3 Relaxation and Linewidths

Two relaxation time studies on both ⁹⁹Ru and ¹⁰¹Ru have been published. One is a determination of the ratio ¹⁰¹Q/⁹⁹Q; the second reports the variation of *T*₁ with temperature. Both have been done on RuO₄. An interesting study of the ligand exchange in Ru(H₂O)₆²⁺, using ⁹⁹Ru, has been done as a function of temperature. The linewidths range from a few up to 800 Hz. They depend on temperature and the different extent of chemical exchange between the complexes and the solvents.

4.8 Lanthanum

Two isotopes are available for NMR spectroscopy.^{1,2,4–6} The first, ¹³⁸La with spin +5, has a relatively high quadrupole moment of 0.450 × 10^{−28} m² and an extremely low natural abundance of 0.09%, and is cited here only for completeness. Its Ξ value is 13 194 267 Hz. The second, ¹³⁹La with spin + $\frac{7}{2}$, a natural abundance of 99.91%, and a quadrupole moment of 0.200 × 10^{−28} m², is the only isotope used in NMR.

As for scandium, the NMR interest of lanthanum is limited by its chemistry, which has mainly developed for La³⁺ ions.

4.8.1 Chemical Shifts

The reference is La(H₂O)_n³⁺ in D₂O. The Ξ value of ¹³⁹La is 14 125 605 Hz. The observed chemical shift range is between +1090 and −772 ppm. The lanthanum cation gives solvated species or weak complexes, so that most of the reported studies are focused on the problem of outer and inner coordination spheres, which can be summarized by the equation

For these samples, the lanthanum chemical shifts depend on concentration and solvent. An isotopic effect of −1.6 ppm has been observed between H₂O and D₂O solutions. Some tentative relationships between δ(La) and the nature of the ligand have been proposed.

Lanthanum complexes with proteins have been studied, and the exchange rates of ligands have been measured between 273 and 326 K and up to 200 MPa. Such equilibria have also been confirmed by 2D EXSY experiments.

To the best of our knowledge, no coupling constants are known.

4.8.2 Relaxation and Linewidths

Some relaxation time measurements have been performed and have been used for the study of exchange processes. *T*₁ values are usually less than milliseconds. The narrowest linewidth is 22 Hz, but usually they are in the range of 200–2000 Hz, with a maximum of 11 800 Hz.

5 THE WELL-STUDIED NUCLEI

5.1 Vanadium

With its high receptivity ($D^P = 0.38$), low quadrupole moment ($-0.052 \times 10^{-28} \text{ m}^2$), and high natural abundance (99.76%), ^{51}V , with spin $+\frac{7}{2}$, is the most widely studied transition metal. Numerous reviews^{1,3–6} have appeared, the most documented being that of the Hamburg group.^{6,26}

Vanadium also has another NMR-active isotope: ^{50}V , with spin $+6$, a natural abundance of 0.24% (and therefore a very poor receptivity), a moderate quadrupole moment of $+0.210 \times 10^{-28} \text{ m}^2$, and a Ξ value of 9 970 314 Hz for neat VOCl_3 . This isotope has only been studied in some relaxation experiments to determine the ratio $^{50}Q/^{51}Q$. We shall now focus our attention only on ^{51}V .

5.1.1 Chemical Shifts

The universally adopted reference is neat VOCl_3 , which has a Ξ value of 26 302 961 Hz. The observed chemical shift range is between +2375 and -2052 ppm . The ranges corresponding to the different oxidation states largely overlap, and cannot be used for oxidation state determination. Attention must be paid to neighboring nuclei: ^{63}Cu , +8080 ppm; ^{23}Na , +5660 ppm; ^{123}Te , -5060 ppm ; and ^{27}Al , -9350 ppm . A summary of the chemical shifts according to the chemical nature of the molecule is presented in Figure 3.

Two classes may be distinguished: the V(V) compounds, with d^0 closed shell structure, and the other oxidation states +III, +I, 0 and $-I$, with d^4 or d^6 open shells.

Figure 3 Chemical shift ranges of ^{51}V relative to VOCl_3 . Open bars correspond to closed-shell d^0 and shaded bars to open-shell d^n complexes. Black bars correspond to complexes with π -bonded ligands. (Reproduced by permission of Elsevier from D. Rehder, in *Transition Metal Nuclear Magnetic Resonance*, ed. P. Pregosin, Elsevier, Amsterdam, 1991, Chap. 1)

Figure 4 ^{51}V 2D EXSY NMR spectrum of a solution containing 10 mM vanadate, 1.0 M KCl, and 20% D_2O at pH 8.6. (Reproduced by permission of the American Chemical Society from D. C. Crans, C. D. Rithner, and L. A. Theisen, *J. Am. Chem. Soc.*, 1990, **112**, 2901)

The first class, V(V), comprises mainly vanadates, thiovanadates, peroxovanadates, and heterovanadates, and here ^{51}V NMR has been important in increasing the understanding of this complex chemistry. 2D COSY or EXSY experiments have been used, as shown by the example in Figure 4. The temperature effect on the chemical shifts is small, except for the cases where chemical exchange occurs. Isotope effects have been observed with $^1\text{H}/^2\text{D}$ or $^{16}\text{O}/^{18}\text{O}$ replacement, which leads to low-frequency shifts of -0.73 ppm for the former and -0.19 ppm for the latter.

The evolution of the chemical shifts according to the steric effect is not yet clear, but the electronic effect is better understood, and is related to the HOMO–LUMO splitting ΔE . The d^0 structure gives rise to what is called an ‘inverse’ behavior—for instance, according to the halogen effect.⁹ For V(V) derivatives of biological molecules, ^{51}V NMR has been widely used.

The second class comprises all other oxidation states, which have a ‘normal’ behavior according to their d^4 or d^6 electronic structures. This series includes the cyclopentadienyl complexes [V(I)] and the carbonylvanadates [V(–I)]. Some V(III) complexes have been studied. Complexes of the second class have resonances that are very sensitive to temperature and isotopic substitution. Temperature coefficients of $0.3\text{--}1.5 \text{ ppm K}^{-1}$ have been observed. The substitutions $^1\text{H}/^2\text{D}$, $^{12}\text{C}/^{13}\text{C}$, and $^{16}\text{O}/^{18}\text{O}$ lead to low-frequency shifts of -0.4 to -0.85 ppm , -0.26 to -0.5 ppm , and -0.19 ppm ; these values are calculated for the substitution of one atom. The use of deuterated solvents also has an influence. All these results have been justified theoretically.⁹

5.1.2 Coupling Constants

As the relaxation processes are not very efficient, many coupling constants are known. Two coupling constants of 20.3 and 27.6 Hz are known between ^{51}V and ^1H . $^1J(^{51}\text{V}, ^{19}\text{F})$ lies between 88 and 140 Hz ; these values are temperature-dependent. $^2J(^{51}\text{V}, ^{19}\text{F}) = 10.3 \text{ Hz}$ in $\text{V}(\text{PF}_3)_6^-$. $^1J(^{51}\text{V}, ^{14}\text{N})$ ranges from 92 to 112 Hz . Using ^{17}O NMR on 5% ^{17}O -enriched compounds, $^1J(^{51}\text{V}, ^{17}\text{O})$ has been found between

31 and 64 Hz. The greatest number of coupling constants have been measured with phosphorus, and range from 70 to 655 Hz. They have been discussed in detail.²⁶ An interesting relationship has been proposed between $^1J(^{51}\text{V}, ^{31}\text{P})$ in $\eta^5\text{-(C}_5\text{H}_5\text{)V(CO)}_3\text{PR}_3$ and the isotropic ESR hyperfine coupling constant with ^{57}Fe in $\text{Fe(NO)}_2(\text{PR}_3)\text{Br}$.

Other one-bond coupling constants are known: $^1J(^{51}\text{V}, ^{13}\text{C}) = 116, 124.5$ and 139 Hz in carbonyl derivatives, $^1J(^{119}\text{Sn}, ^{51}\text{V}) = 900$ Hz in $\text{VCp(SnCl}_3\text{)(CO)}_3^{2-}$, and $^2J(^{183}\text{W}, ^{51}\text{V}) = 11$ Hz in $(\text{VW}_5\text{O}_{19})^{3-}$.

5.1.3 Relaxation and Linewidths

There are few direct relaxation measurements apart from those used in conjunction with the observation of ^{50}V . Relaxation times are usually deduced from linewidth measurements.

As ^{51}V has a small quadrupole moment, the linewidths are narrow compared with those of most quadrupolar nuclei. $\Delta\nu_{1/2}$ ranges from 5 to more than 3000 Hz, but values are usually between 100 and 500 Hz. The quadrupolar relaxation mechanism is always dominant. It depends on the symmetry around the vanadium atom, but also on the ligand strength or the bulkiness of the ligands.

Vanadium is the best suited quadrupolar transition metal nuclei for NMR study.

5.2 Cobalt

The description here of ^{59}Co NMR is just a short summary, because this nucleus has the largest published literature among the quadrupolar transition metals. Its well-developed chemistry of complexes, especially of octahedral Co(III) , is a part of the reason for this.^{1-6,15}

Even with its relatively large quadrupole moment of $0.420 \times 10^{-28} \text{ m}^2$, attenuated by the factor $(2I + 3)/I^2(2I - 1) = 0.163$ for its spin $+\frac{7}{2}$, its high receptivity (one-third that of ^1H), and its large chemical shift range of 18 000 ppm, ^{59}Co NMR is of great interest for the chemist. Historically, it was also one of the first observed nuclei, and allowed the discovery of the chemical shift effect.

5.2.1 Chemical Shifts

^{59}Co has the largest chemical shift range of all the Periodic Table. It is then sensitive to all the small influences that a nucleus may experience from its substituents and from its surrounding. The recognized reference is $\text{K}_3\text{Co(CN)}_6$ in H_2O , for which the Ξ value is 23 727 072 Hz, a value that is dependent on temperature, pressure, and concentration. Because of the large chemical shift range, it is sometimes useful to have a secondary reference. This is often Co(acac)_3 , for which the proposed equivalence is $\delta[\text{Co(CN)}_6^{3-}] = \delta[\text{Co(acac)}_3] + 12500$ ppm.

As cobalt is very sensitive to subtle chemical change, and as its chemical shift range is very large, an error of a few ppm is not often chemically significant. All these chemical shifts are solvent-dependent; for instance, an effect of 200 ppm is observed for Co(acac)_3 in different solvents. They are also highly temperature-dependent. A coefficient of -1.38 ppm K^{-1} has been observed for $\text{K}_3\text{Co(CN)}_6$, but this

effect may be larger, and can reach values of -3 ppm K^{-1} with Co(acac)_3 . Concentration has a 'reduced' influence: 20 ppm for the reference between 0.1 and 0.3 M in H_2O . It is clear that such a sensitivity leads to an isotopic effect. From $\text{Co(NH}_3)_6^{3+}$ to $\text{Co(ND}_3)_6^{3+}$, an effect of 5.6 ppm/D is observed. Isotopic shifts have also been reported between normal and deuterated solvents: $-1.05 \text{ ppm H}_2\text{O/D}_2\text{O}$ or $-2 \text{ ppm CH}_3\text{OD/CD}_3\text{OD}$ for $\text{K}_3\text{Co(CN)}_6$.

Co(III) complexes are found at high frequency, most of them between +13 000 and +2000 ppm, with the remarkable exception of the reference $\text{K}_3\text{Co(CN)}_6$. Co(I) , Co(0) , and Co(-I) are found at lower frequencies, generally below 2000 to -4500 ppm. The ranges of the different oxidation states overlap. A large database of observed chemical shifts has been developed by Yamasaki.²⁷ Several laboratories have examined the cobalt resonances in tetrahedral carbonyl clusters MCo_3 (with $\text{M} = \text{Co, Fe, Ru}$), which are found between 0 and -3000 ppm.

Since the beginning of NMR, the chemical shifts of cobalt have been the subject of intensive theoretical studies.⁹ Linear correlations have been interpreted between $\delta[^{59}\text{Co(III)}]$ and the lowest d-d transition energy ΔE . The introduction of the nephelauxetic effect allowed Juranic to find a good linear correlation between $\delta(^{59}\text{Co})$ and ΔE .⁹ Other relations have been found between $\delta(\text{Co})$ and catalytic activity, the relative percentage of isomers in the catalysis product, reaction temperature, and electrochemical data. Lower oxidation states have a $3d^{10}$ electronic structure, and their ΔE values are larger. Consequently, they are less sensitive to chemical changes and have a narrower chemical shift range.

The high sensitivity of cobalt chemical shifts allows determination of the relative abundance of isomers in mononuclear complexes or in clusters (Figure 5). Biological complexes have been studied, among them vitamin B_{12} .

Figure 5 ^{59}Co NMR spectrum of the two isomers of $\text{RuCo}_3(\text{CO})_9(\text{NO})(\mu_4\text{-}\eta^2\text{-HC}\equiv\text{CPh})$. (Adapted with permission of the Royal Society of Chemistry from P. Braunstein, F. Y. Jiao, J. Rosé, P. Granger, F. Balegroune, O. Bars, and D. Grandjean, *J. Chem. Soc., Dalton Trans.*, 1992, 2543)

5.2.2 Coupling Constants

Only a few coupling constants are known, since they are usually small and hidden by the linewidths. $^1J(^{59}\text{Co}, ^{19}\text{F})$ is unknown, since $(\text{CoF}_6)_3^-$ is paramagnetic. $^1J(^{59}\text{Co}, ^{13}\text{C}) = 126\text{ Hz}$ in $\text{K}_3\text{Co}(\text{CN})_6$ and 287 Hz in $\text{NaCo}(\text{CO})_4$. $^1J(^{59}\text{Co}, ^{31}\text{P}) = 1222\text{ Hz}$ in $\text{KCo}(\text{PF}_3)_4$ and between 447 and 840 Hz in phosphine tetrahedral clusters.

5.2.3 Relaxation and Linewidths

The linewidths range from a few hertz to several kilohertz at the limit of detectability. The widths are related to the symmetry around the cobalt atom, and allow distinction between isomers. They have also been used for solvation studies.

There are a few relaxation time measurements. The $\text{Co}(\text{CN})_6^{3-}$ ion has been investigated by several authors. It seems that the origin of the relaxation in this molecule comes from perturbation of the electric field by the asymmetric vibrational modes. For large linewidths, the quadrupolar mechanism is exclusively dominant, but this is not always the case for complexes with long relaxation times. Spin-rotation or scalar mechanisms may be sometimes involved. On high-field spectrometers, the relaxation mechanism arising from the large chemical shift anisotropies has been found to play a role.

5.3 Molybdenum

Two isotopes, ^{95}Mo and ^{97}Mo with spins $-\frac{5}{2}$, and natural abundances of 15.72% and 9.46% , respectively, are NMR-active. Having the higher sensitivity (about three times that of ^{13}C) and the lower quadrupole moment ($-0.022 \times 10^{-28}\text{ m}^2$), ^{95}Mo is the preferred observed isotope. ^{97}Mo , having a large quadrupole moment of $0.255 \times 10^{-28}\text{ m}^2$ and a Ξ value of $6\,673\,711\text{ Hz}$, gives broad bands and is sometimes used in relaxation studies. A large number of results have been published and have been summarized in books¹⁻⁷ and in an excellent review.¹²

5.3.1 Chemical Shifts

The definitively adopted reference is Na_2MoO_4 in a 2 M solution at $\text{pH } 11$, for which $\Xi = 6\,516\,942\text{ Hz}$. At $\text{pH} < 9$, the lines become broader—first by chemical exchange with protons and then by polycondensation processes that give rise to a second broad band. Chemical shifts range between $+4200$ to -3000 ppm , and the domains corresponding to the different oxidation states largely overlap.

Mo(VI) derivatives are observed between $+3200$ and -620 ppm . Molybdates and polyoxymolybdates have been widely studied, as their sulfur analogs or their mixtures. A detailed review may be found elsewhere.^{11,12} All these compounds have resonances that are not very sensitive to concentration, temperature or solvents, since they have d^0 electronic structures.

Mononuclear complexes of Mo(V) are paramagnetic, and are not observed, but the dimers are diamagnetic, and some chemical shifts have been reported, lying between $+320$ and $+985\text{ ppm}$. Their d^1 structure leads to a high sensitivity to the chemical environment.

Only a few results have been published on Mo(IV) , and are mainly devoted to $\text{Mo}_3\text{O}_4\text{L}_9$. Consequently, the known

chemical shift range is limited to between 1165 and 990 ppm . As for Mo(V) , only dimers are observed for Mo(III) species, which have resonances between 3700 and 2400 ppm .

A large number of Mo(II) complexes have been studied. The surprising characteristic is that mononuclear species have chemical shifts that fall between $+315$ and -2100 ppm . The dimeric species are among the most deshielded molybdenum nuclei, and have resonances between $+3200$ and 4150 ppm . In this series, carbonyl and isocyanide complexes are the most studied compounds.

Mo(I) derivatives have resonances between -1856 and $+182\text{ ppm}$, and Mo(0) compounds have been widely studied and have molybdenum chemical shift ranges from -860 to -2130 ppm for the carbonyl derivatives and between $+2270$ to -1585 ppm for the other species. Mixed metal complexes $\text{Cp}(\text{CO})_2\text{LMoHgX}$ have molybdenum resonances in the range -1700 to -1940 ppm . Although most molybdenum derivatives have a normal halogen effect, some Mo(VI) derivatives have an inverse behavior. As molybdenum has many electrons, only approximate theoretical calculations have been performed, which can be used to interpret the observed resonances.⁹ Although for some series, the dependence on ΔE is verified, this is not always the case.

Molybdenum chemical shifts are sensitive to the isomerism of chiral centers when the linewidths are not too large. They have also been used to follow reactions and to analyze mixtures, and are now used for the study of the role of molybdenum in enzymes.

5.3.2 Coupling Constants

A large number of $^{95}\text{Mo}-^{31}\text{P}$ coupling constants are known, especially in Mo(0) complexes. Their values range between 117 and 290 Hz , phosphine ligands having the lowest values. Coupling constants with other nuclei are rare. One $^1J(^{95}\text{Mo}, ^1\text{H}) = 15\text{ Hz}$, one $^1J(^{95}\text{Mo}, ^{19}\text{F}) = 48\text{ Hz}$, one $^2J(^{95}\text{Mo}, ^{19}\text{F}) = 14\text{ Hz}$, and one $^1J(^{95}\text{Mo}, ^{17}\text{O}) = 40\text{ Hz}$ are known. Several coupling constants, ranging between 39 and 46 Hz , have been observed between ^{95}Mo and ^{14}N . Using ^{13}C NMR, a $^1J(^{95}\text{Mo}, ^{13}\text{C}) = 68\text{ Hz}$ has been measured.

5.3.3 Relaxation and Linewidths

Several T_1 studies have been performed on both isotopes, mainly for the comparison of quadrupole moments. Except perhaps in some rare cases, such as $\text{Mo}(\text{CO})_6$, where $T_1 = 7\text{ s}$, the quadrupolar relaxation is dominant and explains the evolution of the observed linewidths according to the symmetry around the molybdenum atom.

6 LANTHANIDES

Apart from ytterbium isotopes and thulium, all NMR-active lanthanides are quadrupolar nuclei, but most exist only in a paramagnetic state, and are not observed in solution. Some are used as paramagnetic shift reagents.

The only lanthanides giving diamagnetic species are ytterbium and lutetium. The former has been observed in solution using its spin- $\frac{1}{2}$ isotope ^{171}Yb . To the best of our knowledge, the quadrupolar isotope ^{173}Yb has never been observed

in solution. Lutetium has two active isotopes. ^{176}Lu has a low natural abundance of 2.6%, a relatively low Ξ value around 8097 kHz, and a very large quadrupole moment of $5 \times 10^{-28} \text{ m}^2$. The second isotope, ^{175}Lu , has a larger natural abundance of 97.4%, a higher resonant frequency $\Xi = 11\,430 \text{ kHz}$, but a large quadrupole moment of $3.5 \times 10^{-28} \text{ m}^2$. These large quadrupole moments have precluded observations.

Some other lanthanides have been observed, but only in the solid state and at low temperature.

7 ACTINIDES

These are all radionuclides, and hence require special equipment for their measurement. The only actinide observed in solution is ^{235}U . Despite its large quadrupole moment of $4.936 \times 10^{-28} \text{ m}^2$, ^{235}U , with a spin $-\frac{7}{2}$ has been observed in neat liquid on a 93.5% enriched sample and on a natural sample at 380 K.²⁸ The Ξ value found is 1841 kHz, and the linewidth of 20 kHz proves the efficient quadrupolar relaxation.

Relaxation measurements of ^{19}F in UF_6 at different temperatures and different frequencies allow an estimation of $^1J(^{235}\text{U}, ^{19}\text{F}) = 4000 \text{ Hz}$. Other studies have been performed in the solid state.

Several other actinides are potentially of interest. ^{239}Pu , with spin $-\frac{1}{2}$, has been subject to some experiments in the solid state. The others; ^{227}Ac ($\frac{3}{2}$), ^{231}Pa ($\frac{3}{2}$), ^{237}Np ($\frac{5}{2}$), ^{241}Am ($\frac{5}{2}$), and ^{243}Am ($\frac{5}{2}$), are produced at a chemical level, and may be used to prepared samples for NMR experiments. The drawback of these nuclei is, as for ^{235}U , their large quadrupole moments of around $4.5 \times 10^{-28} \text{ m}^2$ and their low or very low Ξ values.

8 CONCLUSIONS

Although quadrupolar nuclei are handicapped by their quadrupole moments, this article has shown that at least half of them can be of a considerable interest for the chemist. The availability of stronger magnetic fields will improve the observability of these nuclei—not only by the consequent large increase in sensitivity but also by the fact that on high-field instruments chemical shifts expressed in hertz increase and linewidths remain approximately constant. The result is an increase in resolution. It appears likely that the use of very high fields is the future direction for studies of quadrupolar nuclei to take. As resonances are broad, accurate shimming is not necessary, and these nuclei are less demanding on magnet quality. Because of the large chemical shift range of most of these nuclei, pulse methods may become difficult to use, and new spectroscopic means may have to be found.

1 INTRODUCTION

Zeolites are crystalline aluminosilicates composed of tetrahedra of oxygen anions which surround either a Si^{4+} or Al^{3+} cation. These tetrahedra are arranged such that each oxygen is shared by a neighboring aluminum or silicon atom. Due to an overall stoichiometry of two oxygen anions per tetrahedral center, a net charge of -1 accrues for each aluminum in the zeolite lattice. This negative charge is compensated for by a cation, most commonly a proton or a metal ion of Group IA or IIA. The nature of the cation influences the strength of the acid/base properties of the zeolite.

A great deal of the interest in zeolites stems from the strong Brønsted acidity of the hydrogen forms. Two very important processes are currently carried out over acidic zeolites, the cracking of petroleum and the conversion of methanol to gasolines (MTG process). Petroleum cracking is carried out over hydrogen forms of the faujasite zeolite Y, a medium-pore zeolite comprised of cages with a 1300 pm diameter. Access to these cages is provided by tetrahedrally arranged windows having diameters of 740 pm. Much of the NMR work dealing with the chemistry of olefins is, in part, motivated by the need for a better understanding of the mechanisms of petroleum cracking. The MTG process provides an alternative source of gasoline from methanol, which can be obtained from synthesis gas, itself a product of coal gasification. The MTG process is a relatively recent discovery.^{1,2} It is carried out over the acidic form of the zeolite ZSM-5, a pentasil zeolite having two types of slightly elliptical intersecting channels, one straight and the other sinusoidal. The channel cross-sections are 530 pm by 560 pm and 510 pm by 550 pm respectively. Where the channels intersect a larger void region results.

While both of the above catalytic processes rely on the acidic nature of the zeolites involved, they are also facilitated by the molecular sieving properties of the zeolites. The size and shape of the channels and cages leads to several types of shape selectivity, reactant selectivity, product selectivity, and selectivity caused by restriction at the active site of catalysis.

Most NMR studies of reactions in zeolites have involved the reactions of olefins or alcohols. A prime concern has been the manner in which the acid (or base) properties of the zeolites affect the intermediates and products of these reactions. Shape-selective aspects of the catalysis, particularly those relating to the MTG process, have also been intensely

studied by NMR. With time, olefin and alcohol reactions are accompanied by coking of the catalyst. The formation of coke deposits during reaction has been the focus of several NMR studies. This review will focus primarily on these areas. NMR studies dealing strictly with adsorption into zeolites will not be addressed in this article.

2 REACTIONS OF OLEFINS

While many techniques can be applied to study product distributions over catalysts, very few have the capability of probing the chemistry within a zeolite catalyst. Such internal monitoring provides direct evidence for shape selectivity as well as information on the nature of the adsorbed intermediates in a chemical process. NMR is becoming a very powerful tool for obtaining this type of information.

One of the earliest studies of olefin reactions in zeolites involved low-resolution ^{13}C NMR spectra of ethylene reacting over H-ZSM-5.³ At room temperature immobile polymeric paraffins were evident. When water was added, and the sample heated to 573 K, lighter olefins and paraffins were observed as a product of cracking of the polymeric material.

Van den Berg et al.⁴ applied ^{13}C NMR to the study of a number of adsorbed olefins on H-ZSM-5. These authors adsorbed ethylene, propene, isobutene, and 2-methyl-1-butene at room temperature. The ^{13}C NMR spectra revealed that at 300 K a majority of linear oligomers were formed over the catalyst for all of the adsorbates studied. The average chain length decreased in the series $\text{C}_2\text{H}_4 \gg \text{C}_3\text{H}_6 > i\text{-C}_4\text{H}_8 > 2\text{-methyl-1-butene}$. Some small amounts of branched hydrocarbons were observed with ethylene and isobutene. When ethylene was adsorbed into H-ZSM-5 at 373 K a significant amount of branching occurred and the average chain length decreased. When this reaction was performed over H-mordenite the products were highly branched. The formation of primarily linear chains in H-ZSM-5 was attributed to restrictions due to the pore dimensions. The authors proposed that branched oligomers originally formed at channel intersections and were then linearized through isomerization reactions. The larger pores of the mordenite allowed for branched species.

Zardkoohi et al.⁵ studied the reaction of propene labeled with ^{13}C at the 2-site over both normal and ultrastable ($\text{Si}/\text{Al} = 4$) H-Y zeolite. In this work it was assumed that carbons scrambled via a cyclopropane intermediate prior to oligomerization. Cross polarization with magic angle spinning (CP MAS) was used to acquire the spectra. A peak at 250 ppm was assigned to formation of a carbenium ion $\text{CH}_3\text{C}^+\text{HCH}_3$. Olah's work⁶ with superacids had shown that stationary secondary carbocations should resonate between 300 and 330 ppm. The carbenium ion proposed in this work interacts with zeolitic oxygen, and, because of the typical 80 ppm shift to low frequency (upfield) of oxygenated species such as RC^+OH relative to RC^+R moieties, the shift of 250 ppm was deemed a reasonable one for such a species. The methyl groups associated with the isopropyl cation should resonate at 48 ppm, but this area was obscured by peaks due to oligomers. The authors proposed the following mechanism (Scheme 1):

A peak at 160 ppm was assigned to a dynamic equilibrium between carbons in an ethyl isopropyl carbenium ion and a methyl isobutyl carbenium ion. This resonance position is an

Scheme 1

average of a resonance at 330 ppm due to the carbenium ion and one at 60 ppm due to the methylene. The average value of 195 is consistent with the observed value of 160 ppm if one again considers the low-frequency shift induced by the framework oxygen. A peak also appeared at 70 ppm which was assigned to the carbon at the β position relative to the carbenium center.

Intense peaks at 40 ppm and 30 ppm were assigned to methylene and methyl groups respectively from oligomeric species and carbocations. The intensity of these peaks was higher in H-Y than in the ultrastable H-Y sample due to the blocking of pores by detrital aluminum species in the ultrastable H-Y.

In later work by this group⁷ an apparatus called CAVERN (cryogenic adsorption vessel enabling rotor nestling) was employed for adsorption studies. Propene samples labeled at the 1-, 2-, and 3-positions gave different spectra on H-Y. As a result, label scrambling was not present as had been presumed in their previous study. When [2-¹³C]propene was adsorbed, signals were observed at 250, 143, and 87 ppm. Both single pulse Bloch decays and CP MAS spectra were employed in this study. Signals in the aliphatic region and those of unreacted propene had T_1 values of approximately 80 ms, while the peak at 87 ppm had a T_1 of 2–3 s. The short T_1 values indicated mobile species while the longer T_1 was indicative of a more strongly bound species. In experiments of this type Bloch decays are more quantitative, since they do not depend upon efficiency of magnetization transfer between carbons and protons. In the Bloch decays the size of the signal at 87 ppm was greatly reduced, comprising only about 2% of the spectral intensity. Carbon-13 $T_{1\rho}$ values were equal to 5–10 ms for all species. The CAVERN was loaded and spectra were recorded at temperatures from 213 to 293 K. At 213 K very little propene had reacted. At 253 K the oligomer peak appeared. At 263 K about one-third of the propene had reacted and peaks at 87 and 140 ppm were now evident. At 273 K there was 70% conversion with increasing intensity at 87 and 140 ppm.

The peak at 87 ppm had been previously assigned to those carbons adjacent to the nonequilibrating carbenium ions, which resonated at 250 ppm. However, there was no peak observed at 250 ppm in this series of spectra; therefore, the assignment of the peak at 87 ppm to carbons adjacent to the cation had to be abandoned. A reasonable alternative explanation was to assign the resonance to an alkoxy (alkyl silyl ether) species bound to a zeolite lattice oxygen atom. The peak at 140 ppm was assigned to olefinic carbon atoms of oligomeric species. At room temperature there was complete conversion, and a peak at 250 ppm appeared, which was assigned to a carbocation. When 1-propene was used, two major changes were exhibited: no peak at 87 ppm was observed and, secondly, the aliphatic region extended further to low frequency (indicating a greater contribution of methyl groups). Thus, the carbon atoms in the 1-position ended up in more methyl groups than carbon

Scheme 2

atoms at the 2-position. No scrambling of label was observed. The authors proposed the following mechanism (Scheme 2) to explain these observations:

Upon adsorption, propene forms an alkoxy species. This is followed by Markovnikov addition of a second propene prior to cleavage of the alkoxy. A third propene adds, followed by cleavage, to form a disubstituted olefin. Probable rearrangement of the olefin to more stable olefins occurs in the acidic environment of the zeolite.

This mechanism relied heavily on the assignment of the peak at 87 ppm to the alkoxy. To support this assignment the authors noted that the intensity of this peak did not correlate at all with the peak at 250 ppm assigned to the carbocation. Also, upon exposure of the sample to moisture, there was a loss of intensity of the resonance at 87 ppm and formation of a peak at 67 ppm. A peak at 67 ppm is consistent with secondary ethers or alcohols having the hydroxyl group in the 2-position, but not from primary or tertiary alcohols. The expected product from the alkoxy would be an alcohol with the hydroxyl group in the 2-position. The peak at 67 ppm survived interrupted decoupling of 50 μ s, while that at 87 ppm did not. This suggested that the species resonating at 87 ppm was an immobilized, protonated carbon. The peak at 87 ppm was never observed with 1- or 3-propene. This finding rules out a long-lived carbocation which would surely scramble. The shift of this peak was about 20 ppm to high frequency from that expected for an alkyl silyl ether. However the presence of a nearby Al atom and the incipient carbocation nature of the species may explain the high-frequency shift. Low-temperature experiments confirmed that propene itself was mobile in the zeolite at low temperatures and could diffuse to form alkoxy intermediates.

The assignment of the peak at 250 ppm to a nonequilibrating carbocation, is now believed to be incorrect. The interaction between the carbocation and the zeolitic oxygen atom is apparently so strong that an alkoxy is formed. For a long-lived carbocation to exist in the zeolite it cannot interact with an oxygen atom and must be stabilized in some way. The authors suggested that olefins are formed, and then undergo hydride abstraction and cyclization, as is observed in the conjunct polymerization of alkenes. In this process alkanes are formed at the expense of hydrogen from the olefins, which in turn are converted into alkyl cyclopentenyl cations. The proposed cations contain carbons that should resonate at 249 and 158 ppm.^{8,9} If this assignment is correct there should be a correlation between intensity at 158 ppm and 250 ppm. Careful examination of their spectra show this to be the case. The peaks appear at a roughly 2:1 intensity ratio as expected. The same alkoxy intermediate was observed by Aronson et al.¹⁰ (see below) upon adsorption of 2-methyl-2-propanol on HZSM-5.

Later work by the Haw group¹¹ involved studies of samples prepared at 298 K by adsorbing both 1- and 2-labeled propene. The samples were then heated in situ to 503 K. After heating, the low-frequency region showed many highly resolved resonances indicative of small mobile species. Resonance shifts and J couplings allowed the identification of isopentane, isobutane, 2,3-dimethylbutane, and propane. The high-temperature spectra of 1- and 2-labeled samples are identical, indicating scrambling of the labels. This is consistent with carbocation mechanisms proposed for high-temperature cracking reactions.¹² The hydrogen necessary for formation of the alkanes from the olefins comes about by coke formation. Coke is observed by CP MAS as a peak between 120 and 140 ppm.

The alkylation of isobutane with 1-butene in LaNaY zeolite was studied by ^{13}C CP MAS NMR.¹³ During the initial feed, all of the butene was consumed and the products were comprised primarily of a mixture of isoalkanes. In the second stage the butene conversion dropped to about 40% and the product distribution changed drastically to isoalkenes, indicating that in the early portion of the reaction the isobutane was being alkylated by the olefin. In the latter stage, however, the olefin was oligomerizing. At higher temperatures the product distributions shifted to lower molecular weights as a result of more pronounced contributions from cracking reactions. Above 220 °C aromatics began to appear.

Butadiene reactions on H-Y and H-ZSM-5 were studied by ^{13}C MAS NMR.¹⁴ Bloch decays were used to probe mobile species whereas CP MAS was used for immobile molecules. Butadiene oligomerizes by primarily 1,4-addition upon adsorption on H-ZSM-5. 1,4-Addition accounts for most of the oligomer in H-Y as well, although 1,2-addition was a minor contributor. As the reaction proceeded there was a loss of intensity in the olefinic region and a corresponding increase in the aliphatic region due to cyclization. These subsequent reactions were zeolite-dependent. In H-Y the linear product underwent cyclization to form fused rings, while isolated rings were formed in H-ZSM-5. Branching reactions and 1,2-enchainment resulted in oligomers with a large methyl group content in H-Y. The 1,4-addition reactions, followed by cyclization, result in pore blockage and catalyst deactivation. No reactive intermediates or carbenium ions were observed.

The Haw group¹⁵ adsorbed acetylene on H-Y and HZSM-5 zeolite. At room temperature no reaction was observed. Upon heating to 473 K, however, two major resonances appeared under CP MAS conditions at 143 and 107 ppm, along with peaks from aliphatic and aromatic carbons (tar). The fact that these reactions were not occurring in the gas phase was confirmed by attempting the reaction over NaY. The authors suggested the species analogous to those observed by Chin and Ellis¹⁶ on alumina (1). Reaction of this sample with water in

the atmosphere produced acetaldehyde. Further heating in atmosphere eventually resulted in acetic acid. Control experiments involving acetylene and water produced tars with a highly paraffinic nature. The hydrogen source for these tars appears to be water. In fact, the amount of tar formed could

be correlated with the degree of hydration of the zeolite. Interrupted decoupling experiments at low and high temperature indicated that the adsorbed species probably undergoes rotation about its O-C bond at 298 K.

The reaction of ethylene over a series of cocation-exchanged Ru-Y zeolites was studied.¹⁷ At room temperature ethylene was converted to ethane and butane on the timescale of days. 2-Butenes appear to be intermediates in the reaction. Coadsorption of hydrogen led to an increase in the initial rate, which was roughly first order with respect to hydrogen. The rate of reaction of ethylene was strongly dependent upon the cocation in the order $\text{Ru-H-Y} > \text{Ru-Ca-Y} > \text{Ru-NaY}$. At intermediate temperatures isomerization of butane to isobutane occurred presumably at acid sites. Above 623 K, carbon-carbon bond cleavage caused methane to be the only detectable product.

Methyl halides were found to convert to hydrocarbons over a large number of faujasite zeolites.¹⁸ Upon adsorption of methyl iodide onto Cs-X a zeolite-bound methoxy species was formed. This species appears at 58 ppm. The assignment of this resonance was proven unequivocally by several NMR methods, including interrupted decoupling, slow MAS, and rotational resonance. Chemical verification was achieved by interacting the adsorbate with water to produce the corresponding alcohol. Ethyl iodide forms the corresponding framework-bound ethoxy species with resonances at 68 and 17 ppm. These peaks also passed all of the criteria for assignment to framework-bound species.

At higher temperatures, both the surface methoxy and the surface ethoxy groups were converted to ethylene, and subsequently to aliphatic moieties. Ethylene did not convert to aliphatic species in the absence of the alkyl iodides over these catalysts. Evidently this conversion of ethylene to aliphatics was catalyzed by HI which was released upon formation of the alkoxy from the alkyl halide.

Methyl chloride and methyl bromide also react in an analogous manner to methyl iodide; however, the concentration of methoxy groups and the reactivity to hydrocarbon synthesis was in the order $\text{CH}_3\text{I} > \text{CH}_3\text{Br} > \text{CH}_3\text{Cl}$. This order of reactivity is as expected for $\text{S}_\text{N}2$ reactions based upon the leaving group ability. One may consider the reaction of methyl halide with the zeolite as attack on the carbon by the nucleophilic oxygen atom of the zeolite lattice, resulting in displacement of the halogen. The basicity of a zeolite increases with the size of the cation. The activity of this reaction should, therefore, increase with increasing size of the cation.

The effect of cation nature on the reaction was investigated. Different cations affected both the activity and the selectivity of the catalysts. NaX was the most active, while K-X and Rb-X were less active than Cs-X. H-X was very unreactive, indicating that activity is not due to acidity. With the exception of NaX, the activities were in line with those predicted by consideration of zeolite basicity. Rb-X was unique in that it showed a high selectivity for olefin and aromatic products. Small shifts in the methyl resonance as a function of the cation were observed. These shifts correlated with activity of the catalyst: the higher the resonance frequency, the more active the catalyst. Cesium-133 NMR showed that the adsorbates interact with the cation sites and that this interaction may be significant in affecting catalyst activity. The framework also affected catalyst activity in the order $\text{Cs-X} > \text{Cs-Y} > \text{Cs-ZSM-5}$.

3 REACTIONS OF ALCOHOLS

NMR has been used extensively to investigate the mechanism of formation of the first carbon–carbon bond in the MTG process. Direct evidence for two types of shape selectivity have been revealed by NMR: product selectivity and active site selectivity.

A study of methanol and ethanol conversion over H–ZSM-5 was undertaken using ^{13}C NMR without MAS.¹⁹ The NMR results were compared with those from gas chromatography. Below 250 °C there was nearly complete conversion of methanol to dimethyl ether. When the temperature was raised to 300 °C there was a loss of intensity in the ether range and an increase in $-\text{CH}_2-$ and $-\text{CH}_3$ resonances. With increasing temperature these peaks shifted to high frequency, indicative of formation of branched chains on aromatic residues. The aliphatic to aromatic ratio of the initially low-temperature adsorbed methanol was 5:1, while a fresh dose of methanol converted directly at 350 °C yielded a ratio of 2:1. It therefore appears that there is competition between aliphatic and aromatic product, rather than a sequential change from aliphatic to aromatic moieties.

Ethanol adsorption at 150 °C yielded diethyl ether. Between 150 and 250 °C an olefinic peak appeared and was assigned to ethylene. Above 250 °C the olefinic peak diminished and an aliphatic resonance formed between 14 and 23 ppm. No distinct aromatic peaks were visible. The authors proposed mechanisms involving carbenium ions.

Carbon-13 NMR studies of methanol on a germanic, near-faujasite zeolite²⁰ showed that methanol reversibly yielded dimethyl ether. Greater conversion occurred at higher temperatures. No other products were observed on the faujasite. Following prolonged heating at 300 °C, a broader resonance appeared underneath that for dimethyl ether (DME) near 60 ppm. This peak was attributed to surface methoxy formation. Peaks due to aldehydes were observed at 193 ppm during reaction of methanol on H–ZSM-5 in the presence of CO.²¹ It was proposed that this signal derives from incorporation of CO via a carbenium ion mechanism.

Carbon-13 CP MAS NMR was used to study the carbonaceous residues formed in H–ZSM-5 and H–mordenite from methanol and ethylene.²² Methanol on H–ZSM-5 yielded a broad distribution of aliphatics including propene, propane, *n*-butane, isobutane, and isopentane. In the aromatic region there was some evidence of benzene, toluene, and xylenes. Over mordenite a much narrower aliphatic product distribution was obtained: only propane, propene, and *n*-butane. The aromatic distribution was, however, broader and included fused aromatics. On both catalysts, surface methoxides were suggested as intermediates. Isoparaffins were more prevalent than linear ones on H–ZSM-5, while on mordenite isoparaffins and C_5 -aliphatics were not seen. Instead, the larger pores of mordenite allowed conversion of C_4 – C_6 olefins into aromatics by mechanisms similar to conjunct polymerization.

Ethylene formed linear chains on H–ZSM-5. The average chain length was 10–12 carbon atoms. Steam cracking of this sample resulted in a large number of C_5 and C_6 residues and some alkylation, as evidenced by the appearance of ethylbenzene. When an ethylene-loaded sample was heated to 573 K in the presence of water, products included the linear paraffins (propane and butane), branched paraffins (isobutane and isopentane), and aromatics (toluene, xylene,

and ethylbenzene). Unlike in the steam-cracked catalyst, xylenes were quite abundant, indicating that they are formed by the conjunct polymerization of olefins.

Kotanigawa et al.²³ studied the adsorption and reaction of methanol on H–Y zeolite by ^{13}C NMR. At room temperature a signal from adsorbed methanol was observed at 48.9 ppm. When the sample was heated to 220 °C four peaks appeared, one of which was derived from the adsorbed methanol. A peak at 59.2 ppm was assigned to a surface methoxyl; however, later work by Anderson and Klinowski²⁴ suggests that this peak was probably due to DME. The two other resonances at 27.2 and 64.7 ppm were tentatively assigned to the methyl carbon of 2-propanol and carbons adjacent to oxygen (either the 2-carbon of 2-propanol or the carbon of a hydroxymethyl group) respectively. Higher temperatures produced surface alcohols as well as a resonance which these authors assigned to a surface epoxy based upon IR data. When 480 °C was reached, olefins were observed. Based upon these assignments the authors proposed that the formation of the first carbon–carbon bond involves a surface methoxyl reacting with a hydroxymethyl group via a carbenium ion intermediate.

Aronson et al.¹⁰ studied the 1:1 adsorption complex of 2-methyl-2-propanol with a Brønsted site on H–ZSM-5. The 2-methylpropanol was labeled at the hydroxyl carbon. Under the conditions of the experiment the adsorbate was dehydrated and the water which was formed desorbed completely, as verified by temperature-programmed desorption (TPD) and thermogravimetric analysis (TGA). Two broad features appeared in the Bloch decay ^{13}C spectra at 80 and 30 ppm in the ratio of 2:3. The peak at 30 ppm indicated that some additional reaction had occurred changing the hydroxyl carbon to an aliphatic one, probably through oligomerization. No peak in the area of 330 ppm was seen, thereby ruling out a carbenium ion resonating in the area reported by Olah.⁶ Furthermore, no line shifts were evident with changes in temperature, thereby ruling out exchange. A small resonance at 123 ppm from carbon–carbon double bonds was observed. Heating of this sample to 373 K resulted in an increase in the intensity and complexity of the aliphatic region. There was a compensatory decrease in the intensity in the 80 ppm region associated with carbons attached to oxygen. Most of the oligomers were still attached to the zeolite in alkyl silyl ethers, since the intensity in the region above 100 ppm remained low. The peak near 80 ppm exhibited an axially symmetric powder pattern with $\sigma_{\parallel} = 93$ and $\sigma_{\perp} = 44$ ppm at 200 K. The isotropic shift was slightly to high frequency from that of the 72.6 ppm shift of the *tert*-butoxide group in bis[(2-ethylhexyl)oxy]di-*tert*-butoxysilane, but to low frequency from the *tert*-butoxide group attached to the more electropositive Ti atom in Ti(*t*-BuO)₄.²⁵ The authors presented a carbenium ion-mediated scheme for formation of some olefinic carbons as well as oligomers (Scheme 3).

The complexity of the spectra in the aliphatic region could not be explained by their scheme. In particular, the appearance of a well-resolved peak at 13 ppm indicates that the labeled carbon has been converted into methyl or methylene groups. This implies rearrangement of tertiary carbenium ions.

From a combination of their TPD–TGA, IR, and NMR work, a potential energy surface was constructed. Reaction proceeds by protonation of the alcohol to form the oxonium ion. This dehydrates to form the alkyl silyl ether via the

Scheme 3

carbenium ion intermediate. The reaction proceeds again through the carbenium ion to the olefin product.

Anderson and Klinowski^{24,26} studied the adsorption and reaction of methanol in H-ZSM-5 zeolite. At room temperature a signal at 50 ppm was observed from adsorbed methanol. Higher pressures of methanol resulted in a second peak due to either vapor or methanol on the outer surfaces of the zeolite. Following heating at 150 °C for 5 or 20 min a resonance at 60 ppm attributable to dimethyl ether appeared. The authors showed via ¹H NMR that this occurs through interaction of the methanol with an acid site in the zeolite. The hydroxyl resonance was shifted to higher frequency by 7.9 ppm upon adsorption, due to formation of a methoxonium ion hydrogen bonded in the intracrystalline space. At larger coverages protonated clusters were formed.^{27,28} The ratio of DME/MeOH was constant with time, indicating that an equilibrium was attained. After treatment of the methanol-loaded sample for longer than 20 min at 150 °C a new resonance appeared at 184 ppm which could be identified as CO. CO was also produced at 250 °C. The production of CO from DME by two different mechanisms has been reported.^{29,30} Both mechanisms, however, involve formation of methane, which was not observed coincident with the formation of CO. CO is formed on ZSM-5 from methanol through a formaldehyde intermediate.³¹

After heating a methanol-treated sample at 250 °C for 54 min and then at 300 °C for 10 min, aliphatic resonances began to appear with a corresponding drop in the DME/MeOH ratio. It would seem that the higher hydrocarbons are either formed preferentially from DME and their formation occurs quicker than the reestablishment of equilibrium between DME and MeOH, or the equilibrium between DME and MeOH (which involves water) is affected by subsequent dehydration reactions. Further heating at this temperature caused complete conversion of methanol and DME to aliphatics and aromatics. Two narrow peaks due to mobile methane and cyclopropane were observed under Bloch decays, but not under CP. Despite spectral overlap, under MAS conditions a large number of products were readily identified, due to the multiplicity of resonances associated with most products. Because CO formed prior to hydrocarbon formation, and its resonant intensity decreased upon formation of hydrocarbon products, the authors suggested that CO was an intermediate in hydrocarbon formation. This was proposed to occur by hydrocarbonylation to ethanol at an iron impurity site, followed by dehydration of ethanol to ethylene. The authors were able to obtain ethylene as the primary olefinic product from an Fe³⁺-exchanged catalyst in support of this suggestion. Haw's group³² tested this hypothesis by carrying out the reaction of methanol over H-ZSM-5 in the presence of CO generated

from formic acid. Carbon-13 from CO was not incorporated in the product hydrocarbon. CO also did not catalyze the reaction of methanol to hydrocarbon as had been suggested by Jackson and Bertsch.³³

An examination of the aromatic region of the NMR spectrum following the 300 °C treatment revealed that the distribution of the adsorbed species during methanol conversion was very different from the product distribution. Product distribution data suggested that primarily *m*- and *p*-xylene, toluene and 1,2,4-trimethylbenzene would be found. The major species found by NMR in the adsorbed phase were, however, *o*- and *p*-xylene and 1,2,4,5-tetramethylbenzene, with smaller amounts of other species including some trimethylbenzenes. These trimethyl species were found in their equilibrium distribution³⁴ in the adsorbed phase, but the larger 1,2,3- and 1,3,5-forms were not found in the product distribution. This was a clearcut example of product selectivity. In ZSM-5 the channel dimensions are 560 × 530 pm; however, more space is available at channel intersections. The larger 1,2,3- and 1,2,5-forms must isomerize to the smaller 1,2,4-form in order to diffuse out of the zeolite. All four tetramethylbenzenes were observed in the catalyst, having been formed at channel intersections. They were not found in the product, again showing product selectivity. The tetramethylbenzenes were not formed in their equilibrium distributions, showing active site selectivity.

At 300 °C signals from the aliphatic region came predominantly from isobutane and propane. Large signals were also observed, however, from *n*-butane, *n*-hexane, *n*-heptane, isopentane, and methane. At 370 °C the number of straight-chain alkanes decreased and larger numbers of branched alkanes were evident. At higher temperatures many larger species were observed in the product distributions due to the larger channel dimensions which allowed diffusion out of the catalyst.

This group also studied methanol adsorption on SAPO-5 and H-ZSM-5 in order to determine the nature of the strong bonding of methanol to Brønsted sites in the zeolites and the conversion of methanol to DME.³⁵ On SAPO-5 at room temperature only mobile methanol was observed. Heating to 150 °C resulted in conversion of about one-third of the methanol to dimethyl ether which was still mobile. Further heating at 250 °C produced two species: methanol and another species exhibiting chemical shift anisotropy due to reduced mobility. The chemical shift suggested either a surface methoxyl or possibly immobile dimethyl ether.³⁶ Heating the sample above 300 °C produced mobile alkenes and aliphatic compounds. By contrast in H-ZSM-5 methanol adsorbed as methanol, but hydrogen bonded to a Brønsted site. The resonance shift remained at 50 ppm in the ¹³C spectra, but the ¹H spectra revealed a hydroxyl resonance near 9.4 ppm. When one methanol was adsorbed per Brønsted site there was considerable line broadening indicating strong bonding. The shift indicated that methanol was still intact. Thus, in H-ZSM-5 methanol strongly adsorbs by hydrogen bonding prior to dehydration, while on SAPO-5 the dehydration precedes the strong binding to the surface. This strong bonding pursuant to dehydration is followed by formation of the C-C bond.

Two-dimensional (2D) *J*-resolved spectroscopy was used to unravel the product distribution of a sample of H-ZSM-5 reacted with methanol for 30 min at 300 °C.³⁷ From the 2D spectrum the authors were able to show that the resonance at 22 ppm had a contribution from the methyl resonance of

isopentane. In later work using 2D spin diffusion NMR³⁸ they showed that this resonance also contained intensity from carbon atoms adjacent to methyl groups in *n*-hexane and *n*-heptane. This work showed the power of 2D techniques in the solid to resolve the many lines in the aliphatic regions of a working MTG catalyst.

Methanol conversion was also studied over SAPO-34.³⁹ The authors discovered an interesting shape selectivity in the chabazite-like structure. At 300 °C treatments many aliphatics up to C₆ were in abundance on the catalyst. This included branched hydrocarbons. Only C₃ and smaller species were present in anything but trace amounts in the product stream, however. Due to the small 380 pm windows to the cages, two types of shape selectivity occur. C₁ and C₂ molecules have unrestricted diffusion. C₃ species are somewhat restricted by occluded hydrocarbons, and C₄ and larger species are diffusion-restricted.

The question of the formation of the first carbon-carbon bond in the MTG process has been a source of great interest. In order to test the hypothesis that the trimethoxonium ion (derived from dimethyl ether) may play a role, trimethyloxonium salts were cation-exchanged into ZSM-5 and the ¹³C NMR spectrum was recorded under CP MAS conditions as a function of time.⁴⁰ The methyl groups of the trimethyloxonium ion resonated at 80 ppm. This signal gradually converted to two overlapping signals at 60 ppm which the authors attributed to surface methoxyl and dimethyl ether. Munson and Haw⁴¹ adsorbed DME on H-ZSM-5. At 293 K a resonance appeared at 80 ppm which could be assigned to the trimethoxonium ion. This species was generated from two dimethyl ether molecules and formed in a 1:1 ratio with methanol. This species could not be seen in methanol adsorption studies due to the shift in the equilibrium toward DME. At high temperatures DME yielded similar products as adsorbed methanol. The observation of this species in H-ZSM-5, while not proving that it is a reaction intermediate, lends some credibility to the Chang mechanism involving deprotonation of the trimethoxonium ion to form the methylenedimethyloxonium ylide.⁴²

A comparison of methanol conversion on straight channel offretites and increasingly tortuous erionite-like zeolites was undertaken.⁴³ The most fault-free (least tortuous) zeolite showed a proclivity for formation of long-chain polymeric hydrocarbons, which were highly branched. A chemical shift at 46 ppm due to tertiary carbons, and a peak at 58 ppm due to quaternary carbons were seen. Formation of these polymeric species was inhibited by the presence of only a few blockages in the channel structure. Channel tortuosity is, therefore, necessary to maintain selectivity to low olefins.

4 COKING

Richardson and Haw⁴⁴ coked samples with a single feed of butadiene at six different temperatures for 1 h. Carbon-13 NMR spectra generally showed two peaks, one due to aliphatics and one due to aromatic and olefinic resonances. The relative size of the aromatic peak increased drastically with treatment temperature. Over 90% of the NMR intensity observed from samples treated above 400 °C was attributed to aromatic species. A sample was heated under butadiene at 150 °C and then subjected to chemical extraction techniques. Virtually all of the coke was unrecoverable, indicating that

the coke comprised large, insoluble, high molecular weight species. Interrupted decoupling experiments confirmed that few carbons were protonated. This result suggests that cross polarization may not be quantitative. Spin counting experiments confirmed that at 150 °C about 80% of the carbon was observable, but that at higher temperatures a significant fraction of the carbon in the coked samples was unobservable.

A number of rare-earth-exchanged zeolites were investigated by CP MAS NMR and relaxation analysis.⁴⁵ Cross polarization was not greatly affected by diamagnetic La³⁺ or those ions having short electron *T*₁ values, including Nd³⁺ and Pr³⁺. For Gd³⁺- and Dy³⁺-exchanged zeolites the ¹H *T*_{1ρ} was drastically decreased, allowing insufficient time for cross polarization. This prevents quantifying coking reactions in these zeolites by CP MAS NMR. The effect was localized. As a result, dilution of the ion concentration in the zeolite allowed spectra to be obtained.

1 INTRODUCTION

Silica (SiO_2) is one of the most abundant materials on Earth.¹ If the wide range of silicate minerals in which silica 'formally' occurs is included, one can account for more than 60% of the Earth's crust in terms of silica. From the industrial point of view, the number of applications of silica is enormous, and we make no attempt to represent them all here. These technological applications of silica include its use in separations (e.g. column chromatography), in composite materials, in consumer products (e.g. as thickening agents), in immobilized reagents (e.g. heterogeneous catalysts), and even in foods. Although a variety of high-surface-area forms of silica are important, including precipitated and fumed silicas, in this article we will focus mainly on samples originating as *silica gels*, i.e. silica samples precipitated from the products of reactions such as:

The materials prepared in this manner tend to have high surface areas and high porosities, although these properties depend substantially on details of the preparation conditions. Most of the technologically important properties of silica depend substantially on the characteristics of the silica *surface*, e.g. the numbers, types, distributions, and reactivities of silanols, i.e. Si-OH groups, at the silica surface.

A priori, it would appear that the spin- $\frac{1}{2}$ nuclides ^{29}Si (4.7% natural abundance) and ^1H ($\sim 100\%$ natural abundance) should be useful for characterizing the silica surface, and possibly also the quadrupolar nuclides ^{17}O ($I = \frac{5}{2}$, 0.04% natural abundance) and ^2H ($I = 1$, 0.02% natural abundance). Clearly, for these quadrupolar nuclides to be useful, isotopic enrichment is required, but that has not been a major difficulty. Indeed, there has been a great deal of NMR work done on silicas and silica-based systems,²⁻⁵ and it would be impossible to review it all comprehensively here, because of reasonable space limitations. Furthermore, because of restrictions on space, it will not be possible to list all of the worthwhile studies in this research area. For these reasons, the convenient approach of emphasizing studies from our own laboratory is adopted, with apologies to those who feel their work may have been neglected.

2 NMR STRATEGIES FOR SILICA SURFACE SELECTIVITY

2.1 The Need

With any NMR experiment on a solid, a technique that provides no major detection advantage to nuclei at the surface will generate spectra that are dominated by peaks due to nuclei that are in positions in the interior (bulk) of a particle, because the number of nuclei that constitute the bulk of a particle will typically be much larger than the number of corresponding nuclei in analogous structural sites at the surface (unless the surface area is very large, say, $\gg 100\text{ m}^2\text{ g}^{-1}$). This intensity dominance by peaks due to bulk sites can be overcome if (1) the nuclei being observed are located only (or largely) at the surface or (2) the method of generating the polarization to be observed discriminates strongly in favor of nuclei at the surface. The former situation often obtains for protons in a typical silica, because most of the protons in such systems exist at the surface as covalently attached $-\text{OH}$ groups (vide infra), as physisorbed H_2O , or as covalently attached structures that result from derivatization processes.

Perhaps the most obvious strategy for preferentially or selectively polarizing surface nuclei in the presence of an overwhelmingly larger number of nuclei in analogous structural sites in the interior would be to use a relaxation reagent that can, at least briefly, interact with the surface and thereby relax the surface nuclei. Although surprisingly little effort seems to have been expended in this direction, one must note the elegant ultra-low-temperature ($\sim 10\text{ mK}$) NMR studies of Waugh and co-workers,⁶ who have used the relaxation effects of ^3He impinging on a surface for the selective relaxation of nuclei at the surface. Other surface-selective (or preferential) relaxation mechanisms would seem possible via the dipolar mechanism of impinging species with large nuclear magnetic moments (say, ^1H or ^{19}F) or even the electron spin magnetic moments of paramagnetic relaxation agents. In the case of paramagnetic surface relaxants, the possibility of dynamic nuclear polarization (DNP)⁷ of surface nuclei from adsorbed paramagnetic species seems attractive, possibly with the Overhauser mechanism operating if the adsorption is rapidly reversible, or the solid state mechanism if the adsorption/desorption process is very slow. Possibilities would also appear to exist for surface-selective relaxation mechanisms based on quadrupolar relaxation of a nuclide with $I > \frac{1}{2}$ (e.g. ^2H or ^{17}O) due to rapid, reversible adsorption/desorption causing a modulation of the local electric field gradient. Recent progress in the surface transfer of ^{129}Xe polarization that has been dramatically enhanced via electron $\rightarrow$ nuclear polarization transfer (e.g. from optically pumped rubidium) is promising for not only providing a surface-selective NMR strategy, but also for providing huge enhancements in the effective sensitivity of NMR detection at surfaces.⁸

2.2 Cross Polarization

To date, the most popular and generally successful surface-selective polarization strategies have been based on $^1\text{H} \rightarrow \text{X}$ cross polarization (CP),⁹ where X is a nucleus present at the surface (and presumably also with the bulk).^{10,11} These strategies are often based on the assumption that essentially all

Figure 1 Cross polarization as a surface-selective strategy, showing only protons near the (hatched) surface region, as covalently attached hydroxyls, physisorbed water, or physisorbed acids (B–H) of some other type. (Taken from Maciel and Ellis⁴)

(or, at least, most) of the protons in the system are present at the surface and on the fact that cross polarization depends upon a static component of the ^1H –X dipolar interaction, which has an inverse cube dependence on the ^1H –X internuclear distance (in many cases the cross polarization rate appears to have an essentially r^{-6} dependence). Cross polarization was developed during the early 1970s by Pines, Gibby, and Waugh.⁹ Its early impact was primarily the dramatic increase in ^{13}C signal-to-noise ratio in NMR experiments on organic solids, which rendered such experiments especially attractive when carried out with magic angle spinning (MAS), as demonstrated first by Schaefer and Stejskal.¹² From the point of view of surface applications, at least as important as the effective increase in sensitivity is the above-mentioned dependence of the cross-polarization rate on internuclear distances. Figure 1 displays the essence of a surface-selective CP strategy, in which only those X nuclei that are close enough to the surface (within, say, 5–6 Å, as represented by the ‘cross-hatched’ area) can be cross polarized by surface protons. The more remote X nuclei in the ‘interior’ or ‘bulk’ of the material are not cross polarized efficiently. Hence, the efficiency, or dynamics, of cross polarization can be used to discriminate in favor of the surface nuclei.

3 $^1\text{H} \rightarrow ^{29}\text{Si}$ CP IN SILICAS

3.1 Silica Gels and Derivatized Silica Gels

In 1980, Sindorf and Maciel^{10,11} published the first high-resolution example of the use of $^1\text{H} \rightarrow \text{X}$ cross polarization for surface-selective X detection in a demonstration of $^1\text{H} \rightarrow ^{29}\text{Si}$ CP in silica gel. Since that time $^1\text{H} \rightarrow ^{29}\text{Si}$ CP has remained the most popular application of this strategy, although there has been significant success with applications to other types of systems. Figure 2 shows typical ^{29}Si spectra of silica gel and related samples obtained by CP MAS (cross polarization and magic angle spinning) and DP MAS (direct polarization, based on ^{29}Si spin–lattice relaxation, not CP). The DP MAS spectrum [Figure 2(a)] of an undried silica gel is dominated by the peak due to $(\text{SiO})_4\text{Si}(\text{Q}_4)$ sites, which represent the bulk (nonsurface regions) of silica particles. The ^{29}Si CP MAS spectrum of an undried silica gel [Figure 2(b)] selects primarily surface sites and shows the following three peaks: a peak at –89 ppm (relative to liquid TMS) due to

Figure 2 ^{29}Si MAS spectra of silica gel samples. (a) DP MAS spectrum of an undried sample. (b) CP MAS spectrum of the same sample as in (a). (c) CP MAS spectrum of a sample dehydrated under vacuum at 209 °C. (d) Sample derivatized with $(\text{CH}_3)_3\text{SiCl}$. (Taken from Maciel⁵)

$(\text{SiO})_2\text{Si}(\text{OH})_2$ (geminal, Q_2) sites; a peak at –99 ppm arising from $(\text{SiO})_3\text{SiOH}$ (single silanol, Q_3) sites; and a peak at –109 ppm from the Q_4 (siloxane) sites near the surface. These peak assignments can be made on the basis of the usual kinds of empirical chemical shift correlations with structure from liquid sample data on silicic acid solutions. However, the dynamics of the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP process can also be used to make these assignments.

Figure 3 shows the results of a variable contact time CP experiment, in which the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP contact period (t_{cp}) is varied in order to elucidate the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP (relaxation) time constant (T_{Hsi}) for each ^{29}Si peak. The early (small t_{cp}) part of such curves is typically dominated by the rate of CP transfer, as characterized by the rate constant T_{Hsi}^{-1} , and the latter part of such curves is usually determined by the rate constant of the rotating frame spin–lattice relaxation of the protons responsible for polarization transfer to the observed silicons, as characterized by the time constant, $T_{1\rho}^{\text{H}}$ (assuming $T_{1\rho}^{\text{H}}/T_{\text{Hsi}}$). These curves can be analyzed mathematically in terms of equation (1),¹³

$$M(t_{\text{cp}})/M^* = \frac{1}{1 - T_{\text{Hsi}}/T_{1\rho}^{\text{H}}} (e^{-t_{\text{cp}}/T_{1\rho}^{\text{H}}} - e^{-t_{\text{cp}}/T_{\text{Hsi}}}) \quad (2)$$

Figure 3 Variable contact time ^{29}Si CP MAS plots for silica. (Taken from Maciel and Sindorf¹⁰)

where $M(t_{\text{cp}})$ is the ^{29}Si magnetization generated by ^1H – ^{29}Si CP as a result of a CP contact period t_{cp} , and M^* is the ‘ideal’ maximum ^{29}Si magnetization that would be generated if $T_{1\rho}^{\text{H}}$ and T_{HSi}^{-1} were both infinite. This analysis shows that T_{HSi}^{-1} for the -89 ppm peak is roughly twice that of the -99 ppm peak, which in turn is an order of magnitude larger than the T_{HSi}^{-1} value for the -109 ppm peak. In terms of the number and distances of nearby protons, the ^{29}Si chemical shift assignments given above in terms of Q_2 , Q_3 , and Q_4 sites are entirely consistent with these T_{HSi} determinations.

3.2 Dehydration of Silica

The ^{29}Si CP MAS spectra collected in Figure 2 also represent two important classes of chemical transformations of silica surfaces that were studied by ^{29}Si CP MAS spectra by Sindorf and Maciel.^{10,11,14–18} Figure 2(c) shows a spectrum obtained on a silica gel sample that has been dehydrated under vacuum at 209°C . One can see in this spectrum the subtle redistribution of peak intensity and the dramatic line broadening relative to the spectrum observed on an ‘air hydrated’ silica gel sample. These changes, especially the line broadening, are presumably due to a redistribution of hydrogen bonding patterns, and perhaps bond angles and bond lengths (and strains) introduced with the removal of the (predominantly physically) adsorbed water of the ‘hydrated’ and essentially ‘annealed’ silica surface represented in Figure 2(b). Such experiments carried out over a wide range of dehydration temperatures, and corresponding rehydration experiments, have revealed valuable information on the effects of dehydration and rehydration on the silica gel surface.

3.3 Silylation of Silica

The ^{29}Si CP MAS spectrum shown in Figure 2(d) represents a sample prepared by the silylation of a silica gel by $(\text{CH}_3)_3\text{SiCl}$. This silylation reaction is a member of an important class of derivatizations of the silica surface, represented by the following chemical equation:

where X represents a labile leaving group (e.g. Cl or OCH_2CH_3) and Si represents a silanol site on the reactant silica surface or a corresponding derivatized silica site in the reacted sample. Such reactions are important, or potentially important, technologically—for the preparation of stationary phases for chromatographic separations, as a means of immobilizing reactive chemical centers (e.g. catalytic sites), in coupling agents for composite materials, and for a wide range of other applications in which it is desired to anchor or ‘immobilize’ a chemically important moiety. Peak d in the spectrum of Figure 2(d), at ca. 10 ppm, is assigned to the trimethylsilyl group covalently attached to the silica surface. Clearly the silylation process has brought about a change of intensities of peaks a, b, and c in Figure 2(b), corresponding to the $(\text{SiO})_2\text{Si}(\text{OH})_2$ or Q_2 sites, the $(\text{SiO})_3\text{SiOH}$ or Q_3 sites, and $(\text{SiO})_4\text{Si}$ or Q_4 sites, at the underivatized surface. At the relatively low level of structural detail represented by the Q_2 , Q_3 , Q_4 notation, the silylation process transforms Q_2 sites into Q_3 sites, and Q_3 sites into Q_4 sites, and these changes are seen by comparing the spectra in Figure 2(b) and (d). By examining such intensity changes systematically, it has been possible to elucidate important reactivity patterns in these systems.^{10,11,14–18} Indeed, ^{29}Si CP MAS NMR, along with supporting data from ^{13}C CP MAS experiments, can serve as an analytical technique for monitoring chemical reactivity

Figure 4 ^{29}Si (right) and ^{13}C (left) CP MAS spectra of silica gel derivatized with $(\text{CH}_3)_2\text{Si}(\text{OCH}_2\text{CH}_3)_2$. (a) Product of reaction with predried silica at 138°C . (b) Product of reaction with predried silica at 240°C . (c) Product of reaction with undried silica at 115°C . (d) Sample (c) heated in air at 150°C . (Taken from Sindorf and Maciel¹⁷)

Figure 5 ^{29}Si CP MAS spectra of APTS-modified silica gels. Each column of spectra corresponds to the drying temperature of silica gel (°C; RT = room temperature) under vacuum prior to reaction in dry toluene, or aqueous reaction conditions (AQ). Postreaction treatment (curing) temperature shown on the left. Structural assignments given at the bottom. (Taken from Caravajal et al.¹⁹)

patterns, e.g. the relative reactivities of the various types of silanols on a silica surface.

The complex chemistry that can occur on a silica surface after silylation by a reagent with more than one leaving group (X), e.g. $\text{RR}'\text{SiX}_2$ or RSiX_3 , is also amenable to study by CP MAS NMR.¹⁷ In the ^{29}Si CP MAS spectra shown in Figure 4 one sees that the product formed initially from the reaction of silica with $(\text{CH}_3)_2\text{Si}(\text{OCH}_2\text{CH}_3)_2$ depends on the reaction conditions and predrying of the silica, and can be converted by the moisture in air [Figure 4(c), (d)] to products in which $\text{Si-OCH}_2\text{CH}_3$ moieties are replaced by Si-OH and ultimately Si-OSi- moieties. In this case, ^{13}C CP MAS spectra are also useful, because they detect the presence and amount of residual $\text{Si-OCH}_2\text{CH}_3$ moieties.

The ^{29}Si CP MAS spectra shown in Figure 5 represent an even more complex derivatized silica system, a series of samples prepared by the silylation of silica with 3-aminopropyltriethoxysilane (APTS) under a variety of conditions (pretreatment temperature = 200 °C for 200 series, or 110 °C for 110 series, 25 °C for RT series, or with silylation carried out in an aqueous slurry, AQ series).¹⁹ APTS-derivatization of the silica surface is of interest for such diverse applications as a variety of composite materials (in which APTS serves as a coupling agent between a silica-like component and, usually, an organic polymer) and for metal complexation agents. One sees from the spectra of Figure 5 that increasing the amount of water in the silylation process or increasing the postsilylation 'curing' temperature brings about changes in attached silane populations from species with

one Si-OSi attachment (-49 ppm) to species with two such attachments (-58 ppm) to three such attachments (-66 ppm). Although ^{13}C spectra are primarily useful for monitoring the residual $\text{Si-OCH}_2\text{CH}_3$ moieties in this system, a careful analysis of the ^{13}C CP MAS spectra of samples corresponding to those represented in Figure 5 reveals that the ^{13}C chemical shift of the central carbon of the pendant $-(\text{CH}_2)_3-$ group originating from APTS is sensitive to protonation or hydrogen bonding of the amino group. ^1H CRAMP spectra (vide infra) and ^{15}N CP MAS spectra are also useful for studying this important issue.

3.4 Fumed Silica

Other types of silicas (and derivatized silicas), besides those based on silica gels, have also been studied by ^{29}Si CP MAS (and DP MAS) experiments, e.g. by Brinker and co-workers^{20,21} and by Legrand and co-workers.^{22,23} Figure 6 shows a comparison of ^{29}Si CP MAS spectra of a fumed silica (a Cab-O-Sil, formed by the vapor-phase combustion of SiCl_4) and a silica gel equilibrated to about the same H_2O vapor pressure.²⁴ The same peaks are present, but they are broader in the case of the fumed silica, and the percentage of surface silica sites that are single silanols is seen to be smaller for the fumed silica than for silica gel. The greater linewidth presumably relates to the greater dispersion of local surface geometries (and chemical shifts) in the Cab-O-Sil structure, which is formed at a higher temperature, and possibly to

Figure 6 ^{29}Si CP MAS spectra of (a) Cab-O-Sil fumed silica and (b) silica gel. Top: experimental spectra. Bottom: individual Q_2 , Q_3 , and Q_4 peaks by deconvolution. Middle: computer sum of the contributions shown at the bottom. (Taken from Liu and Maciel²⁴)

Figure 7 ^{29}Si CP MAS spectra of polysiloxane polymer prepared from $\text{Si}(\text{OEt})_4$ and $(\text{CH}_3\text{O})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{Cl}$ with (a) $\text{Bu}_2\text{Sn}(\text{OAc})_2$ or (b) 0.1 M HCl as catalyst. (Taken from Elnahhal et al.²⁶)

the potential effects of so-called ‘interparticle sites’ at the junctures of the primary particles that contribute to the overall topography of a fumed silica.²³ Detailed studies of ^{29}Si CP MAS spin dynamics of fumed silicas, especially when viewed in relationship to analogous silica gel results, appear promising for identifying the main similarities and differences between these two types of silica surfaces.²⁴

3.5 Polysiloxane Systems

There has been a great deal of interest recently in a class of polysiloxane polymers prepared by the hydrolysis

and gelation of mixtures of reagents of the types, $\text{Si}(\text{OR}')_4$ and $\text{RSi}(\text{OR}'')_3$, where R' and R'' are typically methyl or ethyl and R is a ‘pendant’ group that contains some desired chemical moiety, e.g. a specific ligand.²⁵ By varying the nature of R and the ratios of the two types of starting reagents, a wide range of polysiloxane materials, with a broad variety of potentially useful properties, can be prepared. These polysiloxane materials bear a substantial similarity to derivatized (silylated) silicas, with a silica-like three-dimensional network to which the pendant (R) groups are attached. Hence, the NMR techniques that are useful for characterizing derivatized silicas are also useful for these polysiloxane systems.

Figure 7 shows ^{29}Si CP MAS spectra of polysiloxane systems with $-\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl}$ as the pendant group, prepared by the reaction of $\text{Si}(\text{OEt})_4$ with $(\text{MeO})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{Cl}$, using two different catalysts.²⁶ One notes substantially different intensity ratios for the Q_2 , Q_3 , and Q_4 peaks in the two spectra [and possibly a Q_1 peak at about -82 ppm in Figure 7(b)], and for the peaks due to the pendant groups (at about 60 and 65 ppm), as well as a dramatic difference in intensities between the 60 and 65 ppm peaks relative to the Q_2 , Q_3 , Q_4 peaks, for the products from the two catalyst systems employed.

4 $^1\text{H} \rightarrow ^{17}\text{O}$ CROSS POLARIZATION

In addition to cross polarization to ^{29}Si in silica, or to ^{13}C (or ^{15}N , ^{31}P , etc.) in derivatized silicas, cross polarization to ^{17}O in isotopically-enriched silicas has also been illuminating. Oldfield and co-workers have during the past several years made significant progress in the application of solid state ^{17}O NMR techniques for the characterization of inorganic materials. Walter, Turner, and Oldfield²⁷ have demonstrated that $^1\text{H} \rightarrow ^{17}\text{O}$ CP experiments are not only feasible, but they are also very informative from the point of view of editing ^{17}O spectra, by discriminating against ^{17}O signals from oxygen sites with no directly bonded hydrogen. Figure 8 shows $^1\text{H} \rightarrow ^{17}\text{O}$ CP spectra of amorphous silica and a model SiOH system. From a comparison of the spectra obtained from static samples and by MAS, with and without CP, it was possible to assign the ^{17}O signal due to SiOH groups at the surface.

5 PROTON NMR APPROACHES

5.1 Dipole–Dipole Broadening

High-resolution ^1H NMR spectroscopy has proved to be highly useful in studying the surfaces of silicas and a variety of other solids. In order to obtain high-resolution ^1H NMR spectra of solids (including their surfaces), it is necessary to average not only the chemical shift anisotropy (easily done by MAS), but also ^1H – ^1H dipolar interactions.^{28,29} The latter can be very large (tens of kHz). Magnetic dipole–dipole interactions manifest an inverse cube dependence on internuclear distance. Therefore such interactions, and the ^1H – ^1H spin–spin flip-flops that they can generate, are especially strong if the protons are situated in close proximity to each other, e.g. in a typical organic solid, but also perhaps in hydrogen-bonded clusters of hydroxy groups on a surface. Hence, a priori one can feel confident that moderate-speed MAS experiments (say, less

Figure 8 Static and MAS ^{17}O spectra of amorphous SiO_2 and polycrystalline $(\text{C}_6\text{H}_5)_3\text{SiOH}$ obtained at 67.8 MHz. (a) ^1H -decoupled static spectrum of SiO_2 without CP: 108 scans. (b) ^1H -decoupled MAS spectrum: 100 scans, 7.6 kHz spinning speed (*indicates spinning sidebands). (c) $^1\text{H} \rightarrow ^{17}\text{O}$ static spectrum of SiO_2 , 200 scans, 0.1 ms contact time. (d) $^1\text{H} \rightarrow ^{17}\text{O}$ MAS spectrum of SiO_2 , 200 scans, 0.1 ms contact time. (e) ^1H -decoupled static spectrum of $(\text{C}_6\text{H}_5)_3\text{SiOH}$ without CP: 500 scans. (f) ^1H -decoupled MAS spectrum of $(\text{C}_6\text{H}_5)_3\text{SiOH}$: 800 scans, 4.0 kHz spinning speed. All spectra were obtained using a 2 s recycle time. (Taken from Walter et al.²⁷)

Figure 9 The multiple pulse line-narrowing strategy for averaging homonuclear dipolar interactions. Each rectangle [between (a) and (b)] represents one multiple pulse cycle (e.g. four pulses for WAHUA, eight for MREV-8 or 24 for BR-24). There is one data acquisition point for each cycle (e.g. between each rectangle). (Taken from Maciel⁵)

than 20 kHz) are adequate for studying silica surfaces only for substantially dehydrated samples. For nondehydrated or nondeuterated samples, in which the *local* surface density of protons can be substantial, multiple pulse techniques may be required for eliminating the line-broadening effects of ^1H - ^1H dipolar interactions. Alternatively, a useful strategy employed by Vega and co-workers is to ensure that the ^1H concentration is small by exchanging protons at the surface with deuterons.³⁰

5.2 Multiple Pulse Line Narrowing: CRAMPS

In 1968, Waugh and co-workers³¹ introduced a *multiple pulse* approach for averaging strong homonuclear dipolar interactions. The strategy of this kind of approach is that, over the *entire* period of each individual multiple pulse cycle (four 90° pulses in the original work), the average Hamiltonian that governs the evolution of the spins over the entire cycle does not include the homonuclear dipolar interaction. A nonvanishing chemical shift effect, albeit scaled down, is present in the average Hamiltonian. Hence, if one acquires one data point stroboscopically between each adjacent pair of multiple pulse cycles in a long string of such cycles, the resulting time-dependent signal (analogous to a free induction decay) is

Figure 10 ^1H NMR spectra of citric acid. (a) Static sample, single pulse, (b),(c),(d) MAS-only with indicated MAS speed. (e) and (f) CRAMPS. (Taken from Dec et al.³⁵)

modulated by chemical shift effects, but not by homonuclear dipolar effects. The strategy is outlined in Figure 9 in which each rectangle represents a multiple pulse cycle and each asterisk represents a data acquisition point. The bandwidth of the experiment depends on $1/t_c$, the inverse of the multiple pulse cycle time.

The original homonuclear line-narrowing pulse sequence (WAHUA)³¹ was a four pulse sequence; later elaborations involve more pulses in the total cycle and offer compensation for pulse imperfections and/or higher order averaging of the homonuclear dipolar interaction.^{32,33} In general, this class of experiments requires short ($<1.5\ \mu\text{s}$), powerful 90° pulses with precisely defined phases and until recently has been technically one of the most difficult experiments in the solid state NMR laboratory. Currently, the most popular multiple pulse sequences are the eight pulse MREV-8 sequence³² and the 24 pulse BR-24 sequence.³³

For powdered or amorphous samples, in order to avoid line broadening due to chemical shift anisotropy, magic angle spinning is employed (which also averages various heteronuclear dipolar couplings). Gerstein and co-workers³⁴ were the first to combine a multiple pulse homonuclear

Figure 11 ^1H NMR spectra of untreated silica gel. (a) Static sample, single pulse. (b),(c),(d) MAS-only with indicated MAS speed. (e) CRAMPS. (f) CRAMPS on an expanded scale. (Taken from Dec et al.³⁵)

line-narrowing technique with magic angle spinning, and introduced the acronym CRAMPS for Combined Rotation And Multiple-Pulse Spectroscopy.^{28,29}

5.3 ^1H CRAMPS Studies of Silicas

Figures 10 and 11 show the difference in ^1H line-narrowing capabilities between CRAMPS and MAS-only (no multiple pulse sequence) with a modestly high MAS speed (10–11 kHz).³⁵ For powdered crystalline citric acid (Figure 10), one sees six distinctly resolved ^1H CRAMPS peaks, but essentially no resolution in the 10.7 kHz MAS-only ^1H spectrum. This difference reflects the high proton concentration (~ 29 atom %) and molecular rigidity of crystalline citric acid. For the more proton-dilute (~ 2.5 atom %) silica gel system (Figure 11), the ^1H NMR experiment yields a modestly narrowed ^1H spectrum even on a static sample, and 4.7 kHz MAS yields a spectrum that is superficially similar to that obtained by CRAMPS. However, close inspection reveals important details that differentiate the ^1H spectra obtained by these two techniques [Figure 11(d) and (e)]. All of the remaining ^1H spectra discussed in this article were obtained by the CRAMPS technique.

One should note that the CRAMPS technique is not necessarily a panacea for ^1H NMR studies on surfaces, or for any other type of sample. Dynamics associated with motion and/or chemical reactions with a time constant that is comparable to the cycle time (t_c) of the multiple pulse sequence interferes with the multiple pulse averaging of

^1H – ^1H dipolar interactions.^{29,36} Of course, an analogous problem can also arise with magic angle spinning, for which the critical period is ν_{MAS}^{-1} , where ν_{MAS} is the MAS frequency.³⁷ To quench this kind of dynamic interference with the line-narrowing efficiency of any cyclic technique, like MAS and/or a multiple pulse sequence, one can try to alter the dynamics, e.g. by changing (usually lowering) the sample temperature.

As an example of the application of the ^1H CRAMPS technique to the study of silica surfaces,³⁸ Figure 12 shows the ^1H CRAMPS spectra obtained on untreated [Figure 12(a), (a'), (a'')] and dried [Figure 12(b), (c), (d)] silica gel samples. Comparison of spectra (a) and (b) show that the relatively sharp peak at about 3 ppm in the spectrum of an untreated silica is removed by moderate dehydration; this peak is therefore identified as physisorbed water. The broad nonsymmetrical peak that is largely to the left of the sharp 1.9 ppm peak is unaffected by sample evacuation at 200 °C, but removed by evacuation at 500 °C; this behavior suggests that this peak can be identified tentatively with clustered (or hydrogen bonded) silanols, which are close enough together that suitable dehydration pathways are available. The sharp peak at 1.9 ppm remains after evacuation at 500 °C; this behavior implies that the silanol groups represented by this peak are sufficiently far from each other to make dehydration difficult, so it is assigned to isolated (non-hydrogen-bonded) silanols. These assignments are consistent with 35 years of literature results on liquid solution samples, which show that hydrogen bonding typically reduces proton shielding, and with the reasonable point of view that a wide range of hydrogen-bonding structures exist on a silica surface (chemical shift dispersion: broad peak). These assignments are also consistent with the results of proton dipolar-dephasing experiments, as shown in Figure 13.

5.4 CRAMPS-Based Time Domain Studies of Silicas

Figure 13(a) shows a ^1H CRAMPS version³⁸ of the popular 'dipolar-dephasing' experiment used routinely in ^{13}C CP MAS NMR. In this ^1H CRAMPS version, a 'dephasing period' 2τ is inserted between the initial $\pi/2$ pulse that generates transverse magnetization and the multiple pulse line-narrowing pulse train that detects the transverse magnetization. During the dephasing period, those proton magnetic moments that experience strong dipolar interactions undergo a corresponding degree of dephasing, and the resulting detected signal will be accordingly attenuated. Figure 13(b) and (c) show the results of applying the dipolar-dephasing CRAMPS experiment to untreated silica gel [Figure 13(b)] and to a silica gel sample evacuated at 200 °C [Figure 13(c)]; in both cases one sees that the broad (3.0 ppm) peak is attenuated by a dephasing period (2τ) of 160 μs , whereas the sharp (1.7 ppm) peak is largely unattenuated. From the relationship between hydrogen bonding and proximity (between atoms that participate in a hydrogen bond) and the r^{-3} dependence of dipolar interactions, this dipolar-dephasing behavior provides strong support for identifying the 1.7 ppm peak as arising from isolated (non-hydrogen-bonded) silanols and the broad 3.0 ppm peak as clustered (hydrogen bonded) silanols. This is the same conclusion regarding proximity (and hydrogen bonding) that one would reach from the dehydration behavior shown in Figure 12. It would be difficult to rationalize the elimination

Figure 12 187-MHz ^1H CRAMPS spectra of Fisher S-679 silica gel. (a) untreated; (b) evacuated at 25 °C; (c) evacuated at 200 °C; (d) evacuated at 500 °C; (a'') deconvolution of spectrum (a); (a') computer simulation based on (a''). (Taken from Bronnimann et al.³⁸)

Figure 13 ^1H CRAMPS dipolar-dephasing experiment. (a) Pulse sequence. (b) results for untreated silica gel (showing τ values). (c) Results for sample evacuated at 200°C (showing τ values). (Taken from Bronnimann et al.³⁸)

of water via the ‘dehydration’ of silanols that are *isolated* from each other. Since the physisorbed water peak (3.5 ppm) is only slightly attenuated by the $160\ \mu\text{s}$ dephasing period [Figure 13(b)], one can conclude that water protons experience only weak resultant dipolar interactions, the result of efficient motional averaging.

Other CRAMPS-based ^1H time domain approaches have also been useful in studying silica surfaces. Figure 14 summarizes a CRAMPS-detected T_1^{H} determination on silica gel samples, based on an alternating, two-sequence scheme of the Freeman–Hill type.³⁹ One sees that for each of the two silica samples, untreated (b) and dried (c), all components of proton magnetization relax essentially homogeneously, which suggests that proton spin diffusion among the different spin isochromats is much more efficient than spin–lattice relaxation, which is characterized overall by T_1^{H} values of 0.7–4 s. Furthermore, the marked increase in T_1^{H} that results from sample drying indicates that the physisorbed water in the sample of Figure 14(b) provides an important relaxation source, and is presumably in a rapid state of motion at room temperature.³⁶ Having the ability to establish, via dipolar dephasing, different spin polarizations for hydrogen bonded

Figure 14 ^1H CRAMPS T_1 determination. (a) Pulse sequence, showing individual sequences employed in alternate scans (lower case subtracted from upper case in computer memory). (b) Results for untreated silica gel (showing τ values). (c) Results for sample evacuated at 25°C . (Taken from Bronnimann et al.³⁸)

and isolated silanols, one can explore spin exchange between these two spin sets by an experiment of the type shown in Figure 15(a).³⁸ One sees for the untreated silica [Figure 15(b)] that in a mixing time of a few ms after eliminating ^1H magnetization due to hydrogen-bonded silanols there is a substantial transfer of magnetization (spin exchange) from the isolated silanol reservoir to the hydrogen-bonded silanol protons. In any attempt to interpret or model the structure of the silica surface, the rate of this spin exchange places constraints on the spatial proximities of these two proton spin sets in terms of the dipole–dipole interactions that can be responsible for ^1H – ^1H flip-flops, and/or chemical (H^+) exchange.

Figure 15 ^1H CRAMPS spin exchange experiment. (a) Pulse sequence. (b) Results for untreated silica gel (showing τ_{mix} values). (c) Results for sample evacuated at 200°C (showing τ_{mix} values). (Taken from Bronnimann et al.³⁸)

A variety of CRAMPS-based ^1H NMR experiments of the types represented in Figures 12, 13, 14, and 15 have been carried out on silica samples in which there have been systematic variations of physisorbed water content or dehydration, and often temperature. Figure 16 shows ^1H CRAMPS dipolar-dephasing results obtained at room temperature on three different silica gels.³⁶ The behavior shown is consistent with the ideas described above. Figure 17 shows ^1H CRAMPS spectra of a hydrated (exposed to air) silica gel over a temperature range from 138 K to 298 K.³⁶ An effective freezing point depression of about 45 K can be noted from these kinds of measurements; this result is consistent with previous reports based on other types of experiments.⁴¹

Figure 16 ^1H CRAMPS dipolar-dephasing spectra of three different silica gels. (a) Untreated. (b) Modestly dehydrated (2.6% weight loss). (c) Drastically dehydrated (at 500°C)

5.5 Derivatized Silicas

Figures 18 and 19 show ^1H CRAMPS spectra of silica surfaces that have been derivatized with $(\text{CH}_3)_3\text{SiCl}$ and

Figure 17 ^1H CRAMPS spectrum of an untreated silica gel as a function of temperature, as shown

$(\text{CH}_3\text{CH}_2\text{O})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ (APTS), respectively. These spectra show that this technique can provide a rich level of structural detail on derivatized silica samples. The difference between the spectra of unprotonated and protonated APTS-derivatized samples (Figure 19) is the absence and presence, respectively, of a clearly distinct peak corresponding to the amino group of APTS.²⁹ This difference reflects, at least in part, the interference of ^{14}N quadrupole effects of the $-\text{NH}_2$ group with MAS averaging of ^1H – ^{14}N dipolar interactions. Calculations on $=\text{N}$ – H groups show that, because of the small internuclear N–H distances for directly bonded pairs, very high NMR fields (>1000 MHz) would be required to reduce this broadening to an acceptable level by the ‘brute force’ approach of simply going to a higher field.⁴²

6 CORRELATING ^1H -BASED AND ^{29}Si -BASED INFORMATION

6.1 Complementary Results

While one can distinguish between hydrogen bonded and isolated silanols by ^1H CRAMPS experiments and between single silanols and geminal silanols by ^{29}Si CP MAS experiments, it is important to correlate these two types of information. Ideally, one would base such a correlation on two-dimensional (2D) ^1H – ^{29}Si heteronuclear chemical shift

Figure 18 ^1H CRAMPS spectrum of trimethylsilyl-derivatized silica gel

Figure 19 ^1H CRAMPS spectra of APTS-modified silica gel. Lower, untreated. Upper, treated with HCl. (Taken from Maciel et al.²⁹)

correlation (HETCOR) experiments of the general type that are employed routinely for ^1H – ^{13}C correlation in liquids and more recently in solids.^{43,44} Indeed, Vega has reported such experiments based on $^1\text{H} \rightarrow ^{29}\text{Si}$ CP for the polarization transfer step.⁴⁵ However, as is seen below, rotating frame ^1H spin diffusion among the protons in a typical silica gel during the spin lock state in a $^1\text{H} \rightarrow ^{29}\text{Si}$ CP experiment can substantially scramble what one would hope are discrete $\text{H} \leftrightarrow ^{29}\text{Si}$ CP correlations in the time frame ($>200 \mu\text{s}$) required for relatively efficient CP transfer. Furthermore, the multiple

(Taken from Chuang et al.⁴⁷)

pulse approaches used in ^1H - ^{13}C HETCOR experiments on solids are not very efficient in these ^1H - ^{29}Si systems, although recently reported successes in ^1H - ^{31}P 2D HETCOR experiments on P-O-H systems⁴⁶ indicate that ^1H - ^{29}Si HETCOR in silica may be attractive. In any case, as an alternative to the 2D HETCOR approach, a variety of ^{29}Si -detected ^1H - ^{29}Si CP experiments have been carried out, in which the behavior of protons is monitored by ^{29}Si , establishing the correlation.⁴⁷

6.2 ^{29}Si Detection of Proton Spin Behavior

The simplest such experiment is a ^{29}Si CP MAS experiment in which ^{29}Si detection is carried out *without* proton decoupling. MAS should still average the ^1H - ^{29}Si dipolar interaction during detection, yielding a corresponding sideband pattern to the extent that this interaction behaves inhomogeneously, i.e. to the extent that the ^1H - ^{29}Si dipolar interaction is not altered (by chemical reaction, motion, or ^1H - ^1H flip-flops) during a MAS rotor period.⁴⁷ Figure 20 shows a comparison of spectra obtained with and without ^1H decoupling; it is

clear that the geminal silanol peak suffers most dramatically from the absence of high-power ^1H decoupling, implying that ^1H spin exchange is most efficient in the protons of geminal silanols.

Another ^{29}Si CP MAS experiment useful for correlating ^1H and ^{29}Si spin behaviors is the ^1H - ^{29}Si analog of the common ^1H - ^{13}C dipolar-dephasing experiment. In this technique, rotational and Hahn echo formation occur for a dephasing period (2τ) corresponding to two MAS rotor periods ($2\tau_{\text{rot}}$) for the isotropic ^{29}Si chemical shift, the ^{29}Si chemical shift anisotropy, and the ^1H - ^{29}Si dipolar interaction (to the extent that it behaves inhomogeneously).⁴⁷ Figure 21 shows results of the ^1H - ^{29}Si dipolar-dephasing ^{29}Si CP MAS experiment with the dephasing period ranging over more than $4\tau_{\text{rot}}$. Focusing on the points at $2\tau = 0$, $2\tau_{\text{rot}}$ and $4\tau_{\text{rot}}$, one sees very little dephasing decay for the Q₄ (siloxane) signal, and more efficient decay for the Q₂ (geminal silanol) signal than for the Q₃ (single silanol) signal. This again suggests more efficient ^1H - ^1H spin diffusion among the $=\text{Si}(\text{OH})_2$ protons than among $\geq\text{SiOH}$ protons.

A very direct correlation of ^1H CRAMPS dipolar-dephasing behavior with ^{29}Si CP MAS signals is obtained in the experiment shown in Figure 22, in which there is a 2τ ^1H - ^1H

Figure 21 Plots of deconvoluted peak integrals of the 39.75-MHz ^{29}Si CP MAS NMR spectra of Fisher S-679 silica gel versus ^1H - ^{29}Si dipolar-dephasing time up to four rotor periods. CP contact time, 5 ms; magic angle spinning speed, 2.0 kHz. Vertical dashed lines show odd numbers of rotor periods and vertical solid lines show even numbers of rotor periods. (a) -89 ppm peak (geminal silanols); (b) -99 ppm peak (single silanols); (c) -109 ppm peak (siloxane silicons). (Taken from Chuang et al.⁴⁷)

dipolar-dephasing period *before* CP transfer to ^{29}Si .⁴⁷ Taking account of the rotational echo behavior of ^1H magnetization, for $2\tau = 2nt_{\text{rot}}$ essentially all relevant proton interactions refocus except the ^1H - ^1H dipolar interaction. Hence, the magnetization of those protons involved in the strongest (shortest, least mobile) hydrogen bonds is most effectively dephased during $2\tau = 2nt_{\text{rot}}$ and unavailable for CP transfer to ^{29}Si . Figure 23 shows the results obtained on a silica gel sample. For a CP contact time (t_{cp}) that is small enough ($100 \mu\text{s}$) to avoid the rotating frame spin diffusion that scrambles the desired ^1H - ^{29}Si correlation (vide supra), the geminal silanol peak at -89 ppm is the one that suffers most from ^1H - ^1H dipolar dephasing for a $2t_{\text{rot}}$ period. The effect of rotating frame proton spin diffusion is also clear from the spectra in Figure 23: if a long CP contact period (e.g. 1–5 ms) is employed, essentially the same relative peak intensities are

Figure 22 ^{29}Si CP MAS NMR experiment with ^1H - ^1H dipolar-dephasing prior to $^1\text{H} \rightarrow ^{29}\text{Si}$ cross polarization. (Taken from Chuang et al.⁴⁷)

Figure 23 ^{29}Si CP MAS NMR spectra of Fisher S-679 silica gel obtained with $2 \mu\text{s}$ (top spectrum of each set) and two rotor periods (1.04 ms; bottom spectrum of each set) of ^1H - ^1H dipolar-dephasing prior to four different ^1H - ^{29}Si CP contact times. Magic angle spinning speed, 1.9 kHz. (a) $t_{\text{cp}} = 100 \mu\text{s}$ (top spectrum, 7376 accumulations; bottom spectrum, 82 504 accumulations); (b) $t_{\text{cp}} = 300 \mu\text{s}$ (top spectrum, 2400 accumulations; bottom spectrum, 46 200 accumulations); (c) $t_{\text{cp}} = 1 \text{ ms}$ (top spectrum, 432 accumulations; bottom spectrum, 21 232 accumulations); (d) $t_{\text{cp}} = 5 \text{ ms}$ (top spectrum, 600 accumulations; bottom spectrum, 8320 accumulations). (Taken from Chuang et al.⁴⁷)

obtained whether or not the $2t_{\text{rot}}$ ^1H - ^1H dipolar-dephasing period is included in the experimental sequence.

One overriding theme emerges from all the results embodied in Figures 20–23: the protons that are primarily responsible for cross polarization to geminal silanol silicons are much more extensively involved in hydrogen bonding than are the protons primarily responsible for cross polarization to single silanol silicons. This theme is consistent with structural models of the

Figure 24 Side views of specific silicon planes (dashed line representing an edge of such a plane) of β -cristobalite. Drawing approximately to scale: (a) 111 face; (b) 100 face; (c) vicinal sites from dehydration of the 100 face. (Taken from Chuang et al.⁴⁷)

silica surface (or, at least fragments of it) that correspond to specific faces of a β -cristobalite crystal.^{47,48}

Figure 24 shows views looking 'into' the 111 and 100 faces, which contain single silanols (Q_3) and geminal silanols (Q_2), respectively. From the O–O distances between hydroxyl oxygens of these surfaces, we see that one should expect hydrogen bonding between adjacent geminal silanols, but not between adjacent single silanols; this is in agreement with the NMR results summarized above. Of course, the silica surface is not a homogeneous one, and may be describable as a composite of these two types of surfaces, with suitable interfaces. The geometrical relationship between silanols that are adjacent *across* these interfaces is important in the overall hydrogen-bonding patterns at silica surfaces. Furthermore, the presence of water on the surface dramatically changes the pattern of hydrogen bonding, including the establishment of hydrogen-bonding networks among the single silanols.

7 SUBSURFACE SILANOLS

An implicit assumption on which the use of ^{29}Si CP MAS as a kind of surface-selective technique is based is the following: essentially all (or at least most) of the protons of a sample like SiO_2 are at the surface. This assumption has been tested in a variety of ways, including ^{29}Si NMR. One NMR avenue for testing this assumption is to examine the ^1H and/or ^{29}Si

Figure 25 ^{29}Si CP MAS spectra of silica gels stirred in H_2O or D_2O at 25°C or 100°C , as indicated

NMR spectra of samples that have been subjected to repeated exchanges with D_2O . Figure 25 shows the ^{29}Si CP MAS spectra of silica gel samples that have been treated in this way.⁴⁰ From such studies, it has been determined that for a typical silica gel, 91–97% of the silanols are exchangeable with D_2O , the exact percentage depending on the time and temperature of the exchange. The geminal silanol signal is completely depleted by D_2O exchange, and Figure 26 shows that this signal is immediately restored to its equilibrium intensity shortly after a D_2O -exchanged silica is exposed to the moisture in air. Hence, none of the inaccessible or subsurface silanols are of the Q_2 type.

Extensive studies of spin dynamics in D_2O -exchanged samples have revealed a substantial amount of detail about the local environment and motional dynamics of 'internal' silanols in silica gel.⁴⁰ The T_{HSi} values indicate that the hydroxy groups of 'internal' silanols rotate freely about the Si–O axis in a manner similar to the rotation of non-hydrogen-bonded silanols on a dehydrated silica surface. Analogous studies have also been carried out on a fumed silica Cab-O-Sil.²⁴ While the D_2O -exchange behavior and various features of ^1H and ^{29}Si spin dynamics in Cab-O-Sil are qualitatively similar to what is discussed above for silica gel, some significant and possibly important differences are observed,²⁴ perhaps because of interparticle (particle bridging) silanols that have been suggested by some authors for fumed silicas.

8 SUMMARY AND CONCLUSIONS

MAS NMR approaches based on ^1H and ^{29}Si are enormously useful in the characterization of silica surfaces, including derivatized silica surfaces. The CRAMPS technique, and especially dipolar-dephasing elaborations, provide a powerful way to distinguish between hydrogen bonding and isolated silanols. Silicon-29 CP MAS spectra clearly distinguish between Q_2 , Q_3 , and Q_4 sites at the surface. Via $^1\text{H} \rightarrow ^{29}\text{Si}$ cross polarization, the ^{29}Si CP MAS technique provides avenues for projecting ^1H spin behavior onto a ^{29}Si NMR spectrum. D_2O -exchange approaches allow the use of ^1H and ^{29}Si NMR behavior to examine subsurface or trapped silanols.

1 INTRODUCTION

Though static ^{29}Si CW NMR spectra of quartz, cristobalite, amorphous silica, and silicate glasses were measured as early as 1956,¹ it was more than 20 years before the first systematic study of solid silicates by ^{29}Si MAS FT NMR spectroscopy was accomplished.² Subsequently, the application of this method has grown rapidly and is now a powerful tool in the structural characterization of a wide range of silicate materials. The development is closely related to the great progress made in the 1980s in the instrumentation and methods for the registration of solid state ^{29}Si NMR spectra and their detailed interpretation. Nowadays, high magnetic field strengths and a wide selection of experimental NMR techniques, such as MAS, high-power dipolar decoupling, cross polarization (CP), two-dimensional experiments, and variable temperature measurements, are available on modern solid state NMR spectrometers. Moreover, it was shown even in the initial work on ^{29}Si MAS NMR of silicates and related materials, and has been further confirmed in numerous subsequent studies, that the ^{29}Si chemical shift is most sensitive to the chemical and structural surroundings of the silicon atoms. Chemically and/or crystallographically inequivalent Si sites can thus be detected by distinct resonances in the spectra. Moreover, empirical and theoretical relations have been established between the ^{29}Si chemical shift and the kind, number, and structural arrangement of the nearest and second-nearest neighbor atoms of the silicon atom. Silicon-29 MAS NMR can thus provide detailed information on the local structure around the silicon atoms and is, therefore, a valuable complement to X-ray or neutron diffraction techniques which monitor the periodic long-range order of crystalline materials.

Silicon-29 MAS NMR can also be successfully applied to amorphous or highly disordered solids, the study of which by X-ray diffraction (XRD) techniques is notoriously difficult. It should be emphasized, however, that, at least for crystalline materials, the combination of ^{29}Si NMR and XRD results is often a prerequisite for the reliable interpretation of the NMR

spectra and, also, particularly appropriate for a more complete and detailed description of the structure.

Numerous papers have been published on the application of solid state ^{29}Si NMR to a wide range of crystalline and amorphous silicates and aluminosilicates, and the progress in the field has recently been summarized in several review articles.^{3–5} In addition, a comprehensive review of the fundamentals and applications of ^{29}Si NMR to silicates considering the literature up to 1986 has been presented in a book.⁶ Extensive compilations of ^{29}Si chemical shift data of silicates are given, for example, in Stebbins⁴ and Engelhardt and Michel.⁶

In this article a concise review is given of ^{29}Si NMR spectroscopy of silicates with emphasis on the application of solid state MAS NMR techniques to powder samples. In particular, the characteristic features of the ^{29}Si MAS NMR spectra and the related information on structure and composition of silicates are considered from a general point of view and illustrated by selected examples. However, no detailed discussion on specific classes of silicate materials, such as zeolites, minerals, glasses, and amorphous silica, is presented since other articles in the Encyclopedia are devoted to these subjects (see, e.g. *Molecular Sieves: Crystalline Systems; Geological Applications; Amorphous Materials; Silica Surfaces: Characterization*). To facilitate the subsequent discussions, Section 2 gives a brief introduction to the general structure of silicates and aluminosilicates and the notation used for their description. Section 3 summarizes the pertinent techniques in solid state NMR of ^{29}Si . The general features of the ^{29}Si MAS NMR spectra and their intrinsic parameters are discussed in Section 4, followed, in Section 5 by a survey of the specific information available from ^{29}Si NMR on structure and composition of silicates and aluminosilicates. Finally, applications of ^{29}Si NMR to selected subjects are summarized in Section 6.

2 SILICATE STRUCTURE TYPES

The basic structural units of the silicate framework are SiO_4 tetrahedra which link together in a great variety of ways by sharing the oxygen atoms at their vertices. The resulting configurations can be classified by their topology:⁷ SiO_4 tetrahedra may exist as isolated monomeric anions (nesosilicates), or may be connected by sharing one or two oxygen atoms forming dimeric and trimeric structures (sorosilicates), rings (cyclosilicates), or infinite chains (inosilicates). Single rings and chains may be put together to build up double rings or multiple chains, respectively, and, by linking an infinite number of chains, two-dimensional single layers (layer- or phyllosilicates) are formed. Connection of two or more tetrahedral layers results in the formation of double layers and finally infinite three-dimensional frameworks (tectosilicates). The number of oxygen atoms *not* shared by a second silicon atom ('nonbridging oxygens') determines the negative charge of the complex anionic silicate network, which is balanced by the positive charge of cations located within the interstices of the structure.

Aluminosilicates may be thought of as being formed from silicates by isomorphous replacement of SiO_4 with AlO_4 tetrahedra. The extra charge introduced by the negatively charged AlO_4 tetrahedra must be balanced by additional cations elsewhere in the structure. The distribution of Si and

Al atoms on the tetrahedral sites of the framework may be ordered or disordered and is, in general, governed by Loewenstein's rule,⁸ which suggests that AlO_4 tetrahedra in aluminosilicate networks do not share oxygen atoms ('AlOAl avoidance principle').

Crystalline silicates and aluminosilicates play an important role as rock-forming minerals and as synthetic materials of great industrial and scientific interest. There is also a wide range of disordered or noncrystalline systems, such as amorphous silicates and silicas, gels, and glasses, the structure of which also consists of joined SiO_4 (and possibly AlO_4) tetrahedra, but lacking in any distinct long range order or lattice periodicity. A few silicate structures are known which contain sixfold coordinated silicon, i.e. SiO_6 octahedra (e.g. stichovite, thaumasite), and fivefold coordinated SiO_5 has recently been observed in quenched high-pressure silicate glasses and crystalline CaSiO_3 samples.⁹

For the presentation of the structure of building units or silicate anions in the following, the commonly used Q^n notation is adopted.⁶ In this notation, Q represents a silicon atom bonded to four oxygen atoms forming a tetrahedron. The superscript n indicates the connectivity, i.e. the number of other Q units attached to the SiO_4 tetrahedron in question. Thus, Q^0 denotes the monomer orthosilicate anion SiO_4^{4-} , Q^1 end groups of chains, Q^2 middle groups in chains or rings, Q^3 chain branching sites, and Q^4 three-dimensionally cross-linked groups. A subscript denotes the number of equal Q^n units present in the corresponding silicate anion species. For aluminosilicates the number of AlO_4 tetrahedra bound to the central silicon of a Q^n unit is given in parentheses, e.g. $Q^n(m\text{Al})$ means a SiO_4 group connected via oxygen bridges to m Al and $n - m$ other Si atoms, where $n = 0-4$ and $m \leq n$. In framework aluminosilicates, which are built up exclusively from $Q^4(m\text{Al})$ units, the designation $\text{Si}(n\text{Al})$ is also used. The constitution of the basic Q^n , $\text{Si}(n\text{Al})$, and $Q^3(m\text{Al})$ units is also depicted in Figures 5, 6, and 8 shown in a later section (Section 5.3).

To avoid confusion it should be noted that the general term 'silicate' is often used in this article in its broadest sense, i.e. it may include both silicates (only Si on tetrahedral sites) and aluminosilicates (Si and Al on tetrahedral sites).

3 EXPERIMENTAL NMR TECHNIQUES

Although single crystal (see *Chemical Shift Tensors in Single Crystals*) or static powder ^{29}Si NMR can provide valuable information on local bonding and symmetry in silicates, these techniques have only been applied sparingly. Complete single crystal studies are time consuming and require, at least for work with ^{29}Si in its natural abundance (4.7%), relatively large crystals (usually about 5 mm in diameter), which are normally not available. Static powder studies yield direct information on the anisotropy of the ^{29}Si chemical shift but suffer from broad and often overlapping resonances and also need long measuring times.

The main reason for line broadening in the ^{29}Si NMR spectra of solid silicates is, in general, shielding anisotropy which can be fully averaged by the MAS technique (see *Magic Angle Spinning*). Therefore, the overwhelming majority of solid state ^{29}Si NMR studies of silicates have been performed using MAS of powder samples. The chemical shift anisotropy

for ^{29}Si in silicates is generally less than 100 ppm. Thus, narrow isotropic lineshapes without or with only weak spinning sidebands can be observed at magnetic field strengths B_0 up to 9.4 T by MAS applying spinning frequencies of about 4–6 kHz. Such spinning rates are easily attainable by standard MAS probes with rotors of 7 mm diameter and, if necessary, even spinning rates up to 15 kHz and more can be achieved if smaller rotors (4 mm diameter) are used. Moreover, residual spinning sidebands may be removed by special sideband suppression techniques. If the orientational information available from chemical shift anisotropy data is of particular interest, the three components of the shielding tensor can be retrieved from the detailed analysis of MAS sideband patterns (see *Sideband Analysis in Magic Angle Spinning NMR of Solids*) registered at moderate spinning rates. The MAS technique also averages weak heteronuclear dipolar interactions to distant protons or to other NMR-active nuclei, e.g. ^{27}Al in aluminosilicates. Stronger dipolar couplings of ^{29}Si to nearby protons can be removed by *high-power proton decoupling*.

In addition to MAS and dipolar decoupling, which by the line-narrowing effect result in a considerable improvement of the signal-to-noise ratio of the spectra, the intensities of the ^{29}Si NMR peaks may be substantially enhanced by use of the ^1H – ^{29}Si CP technique, (see *Cross Polarization in Solids* and *Cross Polarization in Rotating Solids: Spin-1/2 Nuclei*), provided that ^1H nuclei capable of polarization transfer to ^{29}Si are present in the sample. In silicates and related materials the most likely candidates for CP are protons of SiOH groups, but under certain conditions also protons of water or organic molecules adsorbed onto porous materials, or functional groups bonded at the silicates surface may give effective CP enhancements. Another advantage of the CP technique is that significantly shorter repetition times for spectral accumulation can be applied since the magnetization recovery of the protons is governed by the longitudinal relaxation time $T_{1\text{H}}$ rather than $T_{1\text{Si}}$, the former being generally much shorter. Beside the gain in sensitivity, ^{29}Si CP MAS NMR spectra may provide valuable information on specific proton–silicon coordinations, e.g. on SiOH groups or more distant $\text{Si} \cdots \text{H}$ interactions (see Section 5.7). However, because the CP efficiency is determined by the cross-relaxation rate T_{HSi}^{-1} which depends strongly on the $\text{Si} \cdots \text{H}$ distance ($T_{\text{HSi}}^{-1} \propto r_{\text{HSi}}^{-6}$), the resulting intensity enhancement in the CP MAS spectra may be rather different for distinct Si sites. Therefore, ^{29}Si CP MAS NMR spectra of silicates are not always quantitatively reliable in the sense of single pulse MAS spectra. For quantitative information from ^{29}Si CP NMR spectra, detailed studies of the CP characteristics by contact time variation and relaxation measurements (T_{HSi} , $T_{1\rho\text{H}}$) are required.

Substantial gains in sensitivity and resolution are further achieved by application of high magnetic field strength B_0 . It is thus generally advantageous to measure ^{29}Si MAS NMR spectra of silicates at high field, e.g. at $B_0 \geq 7$ T, corresponding to resonance frequencies of $\nu_0 (^{29}\text{Si}) \geq 59.6$ MHz.

Structural transformations and dynamic processes in solid silicates and their melts can be profitably studied by ^{29}Si MAS NMR experiments at varying temperatures. In principle, variable temperature MAS NMR measurements in the range of about -100 to $+200^\circ\text{C}$ can be performed with most commercially available MAS probes by cooling or heating the sample via the flowing gas stream used for sample spinning.

However, extension of the range of temperatures applicable in MAS NMR experiments remains a technical challenge. Nevertheless, sample temperatures of up to 600–700 °C have been achieved in special designs of gas- or laser-heated MAS probes. Even higher temperatures have been reached in static NMR experiments, and temperatures up to 1250 °C have been applied to static ^{29}Si NMR investigations of solid and molten silicates.¹⁰

Two-dimensional (2D) NMR techniques are well established in solution studies but have found only limited use so far in solids. There have been, however, several successful studies on the connectivity patterns of tetrahedral Si sites in microporous silica polymorphs with a complex framework structure (see Fyfe et al.¹¹ and references therein) and glasses¹² using the well-known COSY or INADEQUATE pulse sequences. In these studies scalar coupling interactions in the ^{29}Si –O– ^{29}Si connections are used to establish the three-dimensional (3D) connectivities of the silicate framework. In addition, a 2D ^1H – ^{29}Si CP MAS NMR heteronuclear correlation experiment has been proposed which provides specific information on SiOH groups at the silicate surface.¹³ In general, ^{29}Si isotopic enrichment of the samples considerably reduces the measuring times, but 2D ^{29}Si MAS NMR spectra have also been obtained from natural abundance materials, making the method quite generally applicable.

4 GENERAL FEATURES OF THE SPECTRA AND SPECTRAL PARAMETERS

4.1 From Liquids to Solids

Liquid state high-resolution ^{29}Si NMR has been used extensively to study the structure and quantitative distribution of silicate anions present in aqueous silicate solutions of a great variety of compositions (for a review see Chapter III of Engelhardt and Michel⁶). In general, sharp lines appear in the solution spectra, the chemical shifts of which depend sensitively on the specific structural surrounding of the SiO_4 tetrahedra. Characteristic chemical shift ranges were observed for the different Q^n units, and about 20 distinct silicate anion types containing up to 10 silicon atoms could be positively identified by detailed considerations of the shift effects owing to next-nearest and second-nearest Q^n connections, chain length, cyclization, and, in particular, of scalar spin–spin couplings in ^{29}Si isotopically enriched silicate solutions.¹⁴ In addition, the incorporation of aluminum into silicate anions has been proved in highly alkaline, diluted, aluminosilicate solutions.^{6,15}

Clearly, this potential of ^{29}Si NMR to provide detailed information on the silicate structure should be extremely useful if it could also be applied to solid silicates. However, line broadening in solids prevents resolution of distinct signals for structurally different Si sites in the spectra if conventional NMR techniques are used. Therefore, application of MAS and possibly dipolar decoupling is required to narrow the lines, as considered in the preceding section. Although the high resolution of liquid state NMR spectra is normally not attained in solid silicates, well-separated narrow resonances are observed in the ^{29}Si MAS NMR spectra of highly crystalline materials. Moreover, the spectra of solid silicates

are often much simpler than those of silicate solutions since the variety and complexity of silicate anion types is normally greatly reduced in the crystalline solid. A striking example is shown in Figure 1 by the ^{29}Si NMR spectra of a crystalline sodium silicate hydrate and its liquid melt which corresponds to the solution of the same composition.¹⁶ While the crystalline sample exhibits a single line of the monomeric Q^0 unit, the liquid shows a number of resonances representing different silicate anions. On the other hand, specific solid state effects may cause additional line splittings or line shifts not present in the solution spectra, which can provide valuable information on subtle details of the solid structure. This is demonstrated in Figure 2 by the ^{29}Si MAS NMR spectrum of the trimethylsilyl ester of cubic octamer silicate ‘ Q_8M_8 ’ (M denotes the trimethylsilyl group). The spectrum of Q_8M_8 in benzene solution (not shown) exhibits two sharp lines at +12.4 ppm for the silicon in the M group and at –108.6 ppm for the silicon in the Q group, indicating a highly symmetric structure of the Q_8M_8 molecule in solution. In the crystalline solid, the resonances are split into three ($\delta = 11.76, 11.70, 11.50$ ppm) and four ($\delta = -108.34, -108.62, -109.33, -109.68$ ppm) components, respectively, owing to a slight asymmetric deformation of the Q_8 cube in the crystal lattice (resulting in four inequivalent pairs of Q sites) and nonequivalent orientations of the M groups, in full agreement with the X-ray structure.¹⁷ Note also the excellent resolution

Figure 1 ^{29}Si MAS NMR spectra of crystalline sodium silicate hydrate of composition $\text{Na}_2\text{H}_2\text{SiO}_4 \cdot 8\text{H}_2\text{O}$ and its melt. The line assignment to monomer (Q^0), dimer ($\text{Q}^1/2$), cyclotrimer ($\text{Q}^2/3$), cyclotetramer ($\text{Q}^2/4$), and prismatic hexamer ($\text{Q}^3/6$) silicate anions is indicated in the spectrum of the melt.

Figure 2 ^{29}Si CP MAS NMR spectrum of crystalline Q_8M_8 (the cubic octamer silicic acid trimethylsilyl ester, $[\text{Si}_8\text{O}_{20}][\text{Si}(\text{CH}_3)_3]_8$). The inserts are expanded regions of the M and Q signals.

achieved permitting the clear separation of two lines with a chemical shift difference of only 0.06 ppm in this spectrum. Owing to the sharp lines, the large dispersion of the M and Q resonances, the well-defined line splittings, and the dynamics of the CP processes, crystalline Q_8M_8 powder is particularly well suited for checking the spectrometer resolution, setting the Hartmann–Hahn match for CP experiments, and for use as a secondary chemical shift reference.

Although, as shown above, characteristic differences may appear between liquid and solid state spectra, it is important to note that the general relationships between spectral characteristics and structure deduced from the ^{29}Si NMR spectra of silicate solutions also hold for solid silicates and may, therefore, provide a first guideline for the interpretation of the solid state spectra.

4.2 Spectral Parameters

The individual peaks of a ^{29}Si NMR spectrum are characterized by three main parameters, which can be readily extracted from the spectrum: the chemical shift, δ , the intensity, I , and the linewidth, $\Delta\nu_{1/2}$. These parameters are closely related to the structure of the sample being investigated and are preferentially used in structural ^{29}Si NMR studies of silicates. Some general relationships between the NMR parameters and structural features of silicates will be considered below.

4.2.1 Chemical Shift

Most of the structural information that can be derived from ^{29}Si NMR spectra of silicates arises from the chemical shifts. Since δ is dependent on the electronic environment of the ^{29}Si nucleus, it is closely related to the type, position, and bonding characteristics of the surrounding atoms. For silicate structures and related systems, many empirical relationships between δ and structural features have been established, and, at least in part, substantiated by theoretical considerations (see below). In particular, a shift of approximately 10 ppm to lower frequency is generally observed for each newly formed SiOSi connection in a given Q^n environment, while each replacement of silicon with aluminum in a $\text{Q}^n(\text{mAl})$

environment induces a shift contribution of about 5 ppm to higher frequency. Consequently, the central Si atoms of the $\text{Q}^n(\text{mAl})$ units are more shielded with increasing connectivity, n , and decreasing number of Al atoms, m .

Besides the chemical environment, δ further depends on the particular geometry around the Si atom in question. Linear correlations have been established between δ and the mean SiOT ($\text{T} = \text{Si}, \text{Al}$) bond angles, α , nonbonded Si–Si distances, d_{SiSi} , Si–O bond lengths, d_{SiO} , and, for cubic structures, lattice parameters, a_0 , all derived from the X-ray structures of a large number of framework silicates and aluminosilicates. The correlations indicate low-frequency shifts of δ with decreasing d_{SiO} and increasing α , d_{SiSi} , and a_0 .

These dependences could be rationalized by a simple theoretical model (see Engelhardt¹⁸ and references therein) combining quantum chemical calculations with the general shielding theory. In short, the model shows that shielding increases almost linearly with the (positive) net atomic charge, q_{Si} , at the silicon atom, which itself rises with the number of SiOT bridges, n , and decreases with the number of Al atoms, m , of the $\text{Q}^n(\text{mAl})$ environments. This result from the theoretical model is in full agreement with the experimental observations considered above. The q_{Si} value further depends on the degree of s hybridization, ρ , of the oxygen bond orbitals in the four O–Si bonds defining the SiO_4 tetrahedron. Since ρ is related to the SiOT bond angle, α , by $\rho = \cos\alpha/(\cos\alpha - 1)$, and reciprocal to d_{SiO} , the observed correlation with larger shielding at increasing α and decreasing d_{SiO} is confirmed by the theoretical model.

A simple relationship has further been derived between δ and the structures of a large number of silicate minerals and ^{29}Si chemical shifts, which is based on the magnetic susceptibility anisotropy of the bonds to second-nearest neighbors modified by the bond valence and the angle at the bridging oxygen.¹⁹

Finally, it should be noted that δ is further extremely sensitive to the coordination number of the silicon atom. Large, low-frequency shifts are observed in going from four- to five- to sixfold silicon coordination by oxygen (see below).

4.2.2 Line Intensity

In general, the integrated intensities of the peaks observed in a ^{29}Si NMR spectrum are directly related to the number of corresponding silicon atoms present in the sample. Thus, from relative peak intensities the quantitative proportions of the various structurally distinct Si sites can be determined. However, in order to obtain reliable signal intensities, the pulse repetition times and pulse width (flip angle) used in the spectral registration must be carefully selected to avoid saturation due to insufficient spin relaxation between the pulses. The relaxation times T_1 of ^{29}Si in silicates may be rather long in certain cases (up to several thousand seconds) and may differ for different Si sites in the sample. In such cases the pulse timing must be adjusted with regard to the longest T_1 . As mentioned above, the signal intensities of CP spectra are often not quantitatively reliable owing to different CP efficiencies of Si in structurally distinct surroundings.

4.2.3 Linewidth

Provided that instrumental factors, such as inhomogeneity of the B_0 field and missetting of the magic angle or rotor

instabilities, can be excluded, the most likely contributing factors to the linewidth in ^{29}Si MAS NMR spectra of silicates are (i) dispersion of chemical shifts due to structural disorder, distortion, or amorphization of the silicate framework, (ii) residual dipolar interactions of the ^{29}Si nucleus with ^1H , ^{27}Al , or other NMR active nuclei, and (iii) the presence of paramagnetic impurities.

Line broadening by chemical shift dispersion is a very common occurrence in the spectra and is very often the limiting factor for the linewidth. Chemical shift dispersion occurs owing to slightly different environments around nominally equivalent $Q^n(m\text{Al})$ -type silicon atoms characterized by small distortions of bond angles and bond lengths. The latter may be created by lattice imperfections, crystallographic inequivalence, or local distributions of second-nearest and further tetrahedral neighboring atoms, but also by localized cations or other nonframework constituents. Hence, very broad resonances ($\Delta\nu_{1/2} \approx 10\text{--}20\text{ ppm}$) are observed for highly disordered systems, such as amorphous or glassy materials, while narrow peaks ($\Delta\nu_{1/2} \approx 0.1\text{--}3\text{ ppm}$) appear in the ^{29}Si MAS NMR spectra for highly crystalline, perfectly ordered silicates. Insufficient MAS averaging of dipolar interactions with protons of water of hydration or hydroxyl groups can be overcome by high-power proton decoupling. Line broadenings due to dipolar interactions between ^{29}Si and the quadrupolar ^{27}Al nuclei in aluminosilicates may be significant for direct Si–O–Al pairings but are essentially eliminated at B_0 field strengths of 4.7 T or higher. Paramagnetic centers (e.g. heavy metal cations) present in the sample as impurities or constituent parts of the structure can give rise to severe line broadening or may even render the spectrum undetectable, as, for example, observed for samples of olivine with different Fe^{2+} contents.²⁰

5 SURVEY OF INFORMATION ON SILICATE STRUCTURE AVAILABLE FROM THE SPECTRA

In this section the information on local structure and chemical composition that can be derived from the ^{29}Si NMR spectra of solid silicates will be summarized from a general point of view. Unless otherwise stated the following considerations refer to ^{29}Si MAS NMR spectra of microcrystalline samples recorded at high magnetic field strengths and under optimum conditions for maximum spectral resolution and reliable line intensities.

5.1 Number and Population of Si Sites in Nonequivalent Environments

The most direct and rather fundamental information which follows immediately from the number of distinct resonances observed in the ^{29}Si MAS NMR spectra is the number of chemically and/or crystallographically inequivalent Si sites present in the silicate sample. Moreover, from the normalized peak intensities, the relative populations of the various sites can be determined. The number of inequivalent sites that can be distinguished in the spectra depends on the relationship between spectral resolution (linewidth) and chemical shift difference between the distinct resonances. As mentioned above, for highly crystalline samples with well-ordered

Figure 3 ^{29}Si MAS NMR spectrum of tricalcium silicate, Ca_3SiO_5 . (Reproduced by permission of the American Chemical Society from Mägi et al.²¹).

structures, usually very narrow lines are observed, and subtle differences in the structural surrounding of the corresponding Si sites may be detected. Figure 3 shows the ^{29}Si MAS NMR spectrum of highly crystalline tricalcium silicate, Ca_3SiO_5 , a major constituent of Portland cement. The X-ray structure of Ca_3SiO_5 reveals the presence of nine crystallographically distinct Si sites in isolated SiO_4^{4-} tetrahedra (Q^0). In full agreement with this structure, the spectrum exhibits seven clearly resolved lines, two of them with double intensities, for the nine Q^0 environments in the narrow range of -69 to -75 ppm .²¹ In contrast, amorphous, glassy or ill-crystallized samples with highly disordered structures show, in general, broad and overlapping resonances rendering the interpretation of the spectra difficult. However, if sensible assumptions can be made on line positions and lineshapes, the spectra may be analyzed by decomposition and line fitting procedures.

5.2 Coordination Number of Si

The vast majority of silicates contain fourfold coordinated silicon but a number of structures with six-coordinated Si are also known. Silicon-29 MAS NMR can clearly distinguish between the different Si coordination numbers owing to large differences in the ^{29}Si chemical shifts. While δ values between -60 and -120 ppm are typical of four-coordinated SiO_4 in silicates,⁶ the resonances of octahedral SiO_6 coordinations, as observed e.g. in thaumasite, stishovite,²² MgSiO_3 -rich garnets, perovskites, and other high-pressure silicate minerals²³ appear in the range between -170 and -220 ppm . The clear distinction between four- and six-coordinated Si is demonstrated in Figure 4 by the ^{29}Si MAS NMR spectrum of a high-pressure MgSiO_3 sample which exhibits several resonances that could be attributed to the SiO_4 and SiO_6 environments of distinct silicate phases present in this material.²³ Silicon-29 NMR has also revealed the presence of five-coordinated SiO_5 in silicate materials. Weak resonances at about -150 ppm have recently been attributed to SiO_5 in quenched high-pressure alkali silicate glasses and crystalline CaSiO_3 samples.⁹

(Reproduced by permission of the American Association for the Advancement of Science from Stebbins and Kanzaki²³).

5.3 Local Chemical Environment of SiO_4 Tetrahedra

It was shown in Section 4.2.1 that the ^{29}Si chemical shifts of SiO_4 tetrahedra in silicates depend sensitively on type and structural arrangement of the second nearest neighbor atoms at the silicon atom. There are, in particular, two characteristic features which affect the ^{29}Si chemical shift of a SiO_4 group: characteristic shifts to lower frequency are observed with increasing number of SiOT bridges ($\text{T} = \text{Si}, \text{Al}$) formed by the SiO_4 tetrahedron (SiO_4 connectivity), and typical shifts to higher frequencies follow from the replacement of Si with Al in the second coordination sphere of the central silicon (degree of tetrahedral Al substitution). Similar effects have been observed for substitution of tetrahedral Ga in gallosilicates.⁶

A large number of aluminum-free silicates of different degree of SiO_4 connectivity, i.e. neso-, soro-, cyclo-, ino-, and layer silicates and silica polymorphs, have been studied by ^{29}Si MAS NMR, and the resulting ranges of δ for the five Q^n environments are displayed in Figure 5. The increasing shielding with higher degree of SiO_4 connectivity, n , is obvious. However, with the exception of the Q^4 units, the Q^n

Figure 5 Ranges of ^{29}Si chemical shifts of $\text{Si}(\text{O}^-)_{4-n}(\text{OSi})_n$ coordinations (Q^n) in silicates. (Reproduced by permission of Springer-Verlag from Engelhardt and Koller⁵).

Figure 6 Ranges of ^{29}Si chemical shifts of $\text{Si}(\text{OSi})_{4-n}(\text{OAl})_n$ coordinations [$\text{Si}(n\text{Al})$] in tectoaluminosilicates. The dotted lines for $\text{Si}(4\text{Al})$ designate the particularly large range observed for 1:1 aluminosilicate sodalites with different cage fillings.¹⁸ (Reproduced by permission of Springer-Verlag from Engelhardt and Koller⁵).

shift ranges overlap significantly and a simple correlation of δ and Q^n type for a silicate of unknown structure is likely to be risky. Nevertheless, δ may be used as a guide to the Q^n units present, especially if other shift contributions originating from, e.g., cation effects or different geometry are considered.²¹

The characteristic ranges of shift for the five $\text{Si}(n\text{Al})$ (or $Q^4(m\text{Al})$) environments in framework aluminosilicates shown in Figure 6 have been established from a large body of shift data measured in various types of tectoaluminosilicates, silica polymorphs, and, in particular, zeolites. Only Q^4 -type silicons are present in framework silicates but, as in the case of Q^n , the ranges of δ for the $Q^4(m\text{Al})$ units overlap. Nevertheless, the assignment of the usually well-separated lines to the corresponding $\text{Si}(n\text{Al})$ units is, in general, feasible. As an example, Figure 7 shows the MAS NMR spectrum of ^{29}Si in a microporous framework aluminosilicate with an Si/Al atomic ratio of 2.2, i.e. zeolite ZK-5. Five well-resolved resonances are observed which can easily be attributed to the five distinct $\text{Si}(n\text{Al})$ environments by the chemical shifts. Spectra of this type are quite typical for aluminosilicates and do not depend very much on the particular framework structure, at least if no crystallographically inequivalent Si sites are present in the structure. With decreasing Al content (i.e. increasing Si/Al ratio) the intensities shift from the high-frequency lines for $\text{Si}(n\text{Al})$ with higher n to those of the low-frequency $\text{Si}(n\text{Al})$ lines with lower n , and vice versa, i.e., single-line spectra were observed for Si/Al = 1, i.e. $\text{Si}(4\text{Al})$, and for Si/Al = ∞ (SiO_2), i.e. $\text{Si}(0\text{Al})$.

Finally, the typical ranges of δ for the four different $Q^3(m\text{Al})$ tetrahedral units in layer aluminosilicates are displayed in Figure 8. Similar to the tectoaluminosilicates, multiple resonances observed for a certain layer silicate can usually be attributed to the distinct $Q^3(m\text{Al})$ units, despite the overlap of the δ ranges. Besides the aluminum atoms incorporated in the tetrahedral silicate layer, further aluminum may be present in the octahedral sheet which, however, induces comparatively small effects on δ .

Figure 7 ^{29}Si MAS NMR spectrum of zeolite ZK-5, a microporous tectoaluminosilicate of $\text{Si}/\text{Al} = 2.2$. The line assignments to the five distinct $\text{Si}(n\text{Al})$ coordinations are indicated.

Figure 8 Ranges of ^{29}Si chemical shifts of $\text{Si}(\text{OH})(\text{OSi})_{3-m}(\text{OAl})_m$ coordinations [$\text{Q}^3(m\text{Al})$] in layer aluminosilicates. (Reproduced by permission of Springer-Verlag from Engelhardt and Koller⁵).

5.4 Atomic Ratio of Si/Al in the Aluminosilicate Framework

Provided that the NMR spectrum of ^{29}Si in an aluminosilicate is correctly interpreted in terms of the different $\text{Q}^n(m\text{Al})$ units, the atomic ratio of tetrahedral Si and Al in the structure can be calculated from the peak intensities according to the

equation

$$\text{Si}/\text{Al} = \sum_{m=0}^n I_{n,m} / \sum_{m=0}^n (m/n) I_{n,m} \quad (1)$$

where $I_{n,m}$ are the intensities of the $\text{Q}^n(m\text{Al})$ peaks and summation is from $m = 0$ to $m = n$, i.e., from 0 to 3 in layer aluminosilicates and from 0 to 4 in framework aluminosilicates.⁶ The above equation is independent of the specific structure of the aluminosilicate and includes the aluminum which is substitutionally incorporated into the tetrahedral framework, but excludes any nonframework aluminum frequently present, e.g. in layer aluminosilicates and in chemically or thermally treated zeolites. If the total Si/Al ratio of such samples is known from the overall chemical composition, the proportion of nonframework Al can readily be determined.

5.5 Ordering of Si and Al in the Aluminosilicate Framework

For the general case of a random distribution of Si and Al atoms on the tetrahedral sites of an aluminosilicate framework of Si/Al atomic ratio $1/p$, the probabilities of the occurrence of the various $\text{Q}^n(m\text{Al})$ configurations can be calculated by the binomial probability distribution

$$P_{n,m} = \frac{n!}{m!(n-m)!} p^m (1-p)^{n-m} \quad (2)$$

It is obvious that the Si, Al distribution cannot be random if the relative $\text{Q}^n(m\text{Al})$ intensities measured in the ^{29}Si NMR spectrum of a certain aluminosilicate are significantly different from the calculated probabilities. If, however, the calculated populations and observed intensities are similar, then both ordering and disorder are possible. Hence ^{29}Si NMR can disprove random substitution of Si and Al but cannot prove it.

Specific information about the topological Si, Al distribution can be derived by comparing the relative $\text{Q}^n(m\text{Al})$ populations obtained from ^{29}Si NMR peak intensities with model-generated populations. The latter may be derived, e.g. from ordering schemes which are constructed by distributing the respective number of Si and Al atoms on the T sites of a certain repeating unit of the structure. It should be noted, however, that NMR monitors the averaged local environments of the Si atoms throughout the framework and the whole sample volume, which do not, therefore, necessarily imply any simple long-range ordering. Nevertheless, specific Si, Al distributions or, less specifically, the degree of dispersion of Al atoms over the framework has been deduced from the ^{29}Si MAS NMR spectra of a number of zeolites and layer aluminosilicates with different tetrahedral Si/Al ratios. A review of the strategies and methods applied is given in Chapter V of Engelhardt and Michel.⁶ For recent applications see, for example, Herrero.²⁴

5.6 Crystallographically Inequivalent Si Sites

The broad shift ranges observed for the distinct Q^n and $\text{Q}^n(m\text{Al})$ environments (see Figures 5, 6, and 8) indicate

the influence of different bonding geometries around the Si atom on δ , as already discussed in Section 4.2.1. Distinct resonances may thus be observed in the ^{29}Si MAS NMR spectra for Si atoms residing in chemically equivalent $Q^n(\text{mAl})$ environments but occupying crystallographically nonequivalent sites which differ in SiOT bond angles and/or SiO bond lengths. Pertinent examples are the splittings of the Q^3 and M lines in the spectrum of Q_8M_8 (Figure 2), the seven Q^0 lines observed in Ca_3SiO_5 (Figure 3), and the appearance of several resonances in the ^{29}Si MAS NMR spectra of a variety of silica polymorphs and high-silica zeolites,⁶ e.g. the 20 lines observed for the 24 crystallographically inequivalent Q^4 sites in the monoclinic form of silicalite.²⁵ The number and, from line intensities, the relative occupancies of crystallographically distinct Si sites can thus be obtained from the spectra and may be directly related to the results of diffraction experiments. Moreover, for framework silicates the mean SiOT bond angles, α , of the different Si sites can be estimated from δ by applying the quantitative correlations between δ and α considered in Section 4.2.1. These correlations reveal that δ changes by about 0.6 ppm for a 1° change in α . Since, for highly crystalline materials, a peak-to-peak resolution of 0.1 ppm can be achieved in the ^{29}Si MAS NMR spectra, differences in the mean bond angles of about 0.2° may be detected. If the mean bond angles are known from X-ray structure refinements, δ can be calculated which may be helpful in the correct assignment of multiline spectra,¹⁸ as, for example, in the case of the above-mentioned silicalite.²⁶

5.7 Characterization of SiOH Groups in Silicate Materials

It was shown in Section 3 that application of the CP technique selectively enhances the signal intensity of Si nuclei near protons and that the enhancement factor depends on the $\text{Si}\cdots\text{H}$ distance and the CP contact time applied. At short contact times, intense lines of SiOH (e.g. in Q^3 or Q^2 structural groups) are observed, while the signals of Si nuclei with larger $\text{Si}\cdots\text{H}$ distances (e.g. Q^4 adjacent to Q^3) are strongly reduced or do not appear (e.g. Q^4 surrounded only by other Q^4 groups) in the CP MAS spectra. An even more detailed discrimination of the different Si environments can be achieved by application of CP with variable contact times.²⁷ However, as mentioned in Section 3, CP MAS spectra are not always quantitatively reliable. But once the linewidth and position of less abundant species have been determined from the CP MAS spectrum, this information may be used for the quantitation of weak and overlapping lines in the single-pulse MAS spectrum by line fitting procedures.

5.8 Si–O–Si Framework Connectivities

The direct determination of bonding connectivities between the various crystallographically inequivalent SiO_4 sites of a 3D silicate framework has recently become feasible by application of 2D ^{29}Si MAS NMR experiments such as COSY and INADEQUATE¹¹ (see Section 3). The latter experiment has been proved to be particularly useful since only double quantum coherence signals, i.e. only signals due to ^{29}Si nuclei coupled via scalar spin interactions in the ^{29}Si –O– ^{29}Si connection are observed in the 2D plot. This

Figure 9 Contour plot of the 2D ^{29}Si MAS INADEQUATE experiment on high-silica zeolite ZSM-12 with the 1D MAS NMR spectrum shown above. The T site assignments and TOT connectivities are indicated in the spectra. (Reproduced by permission of the American Chemical Society from Fyfe et al.¹¹).

is demonstrated in Figure 9 by the 2D INADEQUATE ^{29}Si MAS NMR spectrum of high-silica zeolite ZSM-12.¹¹ The F_2 dimension is the normal ^{29}Si chemical shift scale while the F_1 domain represents the double quantum frequencies of the resonances. Connected signals occur equally spaced on either side of the diagonal of the plot at the same frequencies in F_2 as the corresponding lines from the simple one-dimensional (1D) experiment. The ZSM-12 structure has seven crystallographically distinct Si sites with equal occupancies in the unit cell which are reflected by the seven lines of equal intensity in the 1D MAS NMR spectrum shown above the 2D plot of Figure 9. All of the nine connectivities expected for the known ZSM-12 structure are observed in the 2D spectrum. The lines may be assigned unambiguously from the expected connectivities by trial and error, but a partial assignment from other data may also be used as a starting point. Such information may be gained, for example, from the expected intensity distribution of the lines, the above-mentioned correlations between δ and SiOSi bond angles, or from different relaxation behavior of particular sites. Other than INADEQUATE, 2D plots from COSY experiments have the normal ^{29}Si chemical shift scale in both F_1 and F_2 and the connectivities appear by cross peaks. However, large intensities along the diagonal occur which may obscure cross peaks close to the diagonal.

So far, 2D ^{29}Si NMR experiments have been mostly applied to high-silica zeolite materials with known structures, and additional details of some of the structures have been revealed. In the case of unknown structures, 2D experiments will make it possible to select between different structural models and to prove or disprove proposed structures or crystallographic space

groups as, for example, shown recently for the low-temperature form of zeolite ZSM-11 and for zeolite ZSM-23.²⁸

Silicon-29 COSY MAS NMR spectroscopy has also been applied to ²⁹Si isotopically enriched sodium silicate glasses and sodium phosphosilicate glasses.¹² The cross peaks observed in the COSY spectra of sodium silicate glasses suggest that a substantial portion of the Q² and Q³ as well as Q³ and Q⁴ silicate sites in the glass are interconnected on a nearest neighbor level. In contrast, no cross peaks were observed for the sodium phosphosilicate glass, implying that the Q⁴ and six-coordinate silicate sites present in this glass are not linked directly together.

6 APPLICATIONS

Important fields of application of solid state ²⁹Si NMR in the various branches of silicate science are listed below. For more detailed information on these topics the reader is referred to the related articles in the Encyclopedia and the selected reviews or research papers from the recent literature cited in parentheses.

1. Zeolites and related microporous materials (see *Molecular Sieves: Crystalline Systems; Microporous Materials and Xenon-129 NMR*, and Fyfe et al.,¹¹ Klinowski,²⁹ Engelhardt³⁰).
2. Mineralogy and geochemistry (see *Geological Applications* and Kirkpatrick,³ Stebbins,⁴ Wilson,³¹ Stebbins³²).
3. Silicate and aluminosilicate glasses (see *Amorphous Materials* and Kirkpatrick,³ Grimmer,³³ Dupree,³⁴ Eckert³⁵).
4. Amorphous silica (see *Silica Surfaces: Characterization* and Leonardelli et al.,²⁷ Pfeleiderer et al.,³⁶ Legrand et al.,³⁷ Chuang et al.³⁸).
5. Cements (see Hjorth et al.,³⁹ Kirkpatrick and Jong,⁴⁰ Tong et al.,⁴¹ Grimmer⁴²).
6. Phyllosilicates and their transformations (see Kinsey et al.,⁴³ Weiss et al.,⁴⁴ Lambert et al.,⁴⁵ Herrero et al.⁴⁶).

1 INTRODUCTION

Silicon is in many respects an important member of the elements. Silicates constitute the main material of the Earth's crust and organosilicon compounds are often found in organic chemistry. This is additional to silicon chemistry proper which has its own new and exciting fields, as for example the formation of a double bond with itself or with other elements. This is reflected in the literature concerning silicon NMR. The fastest growing section comprises the application to materials science and especially solid state silicon NMR. Of the naturally occurring isotopes ^{28}Si (92.21%), ^{29}Si (4.70%), and ^{30}Si (3.09%), only ^{29}Si has a spin $\neq 0$ and a magnetic moment. This puts it in the same league as other elements of Group 14 of the Periodic Table of the elements such as carbon, tin, and lead. There are differences between the techniques as well as the aims in obtaining silicon NMR spectra of silicon compounds in the liquid or dissolved and solid states. For solid state silicon NMR, see *Amorphous Materials*; *Amorphous Silicon Alloys*; *Ceramics*; *Silica Surfaces: Characterization*, and *Silicon-29 NMR of Solid Silicates*.

Because of the immense published material available on silicon NMR, the discussion will be limited to that of review articles and the pertinent references should be looked up there. The only exceptions are recent developments not covered adequately in the reviews. All authors whose accomplishments are only mentioned indirectly in this way are asked for forgiveness.

2 PRACTICAL ASPECTS OF SILICON NMR

The only magnetic isotope of silicon ^{29}Si has a natural abundance of 4.7%, a spin of $\frac{1}{2}$, a magnetic moment of -0.9609 and therefore a receptivity of 3.69×10^{-4} compared with ^1H . It can be characterized as a magnetically diluted isotope of medium sensitivity.¹ Referencing is mostly done relative to $(\text{CH}_3)_4\text{Si}$ (TMS), which has the advantage of having a high volatility, a relatively short relaxation time, and chemical stability, so that it can be added directly to the sample. However, its resonance occurs directly where the resonances of many other organosilicon compounds are found. For this reason, except for precision measurements, the tube

Table 1 Reference Compounds for Silicon NMR

$(\text{CH}_3)_4\text{Si}$	TMS	0.00 ppm
$[(\text{CH}_3)_3\text{Si}]_4\text{C}$		3.6
$[(\text{CH}_3)_3\text{Si}]_2\text{O}$	M_2	7.22
$[(\text{CH}_3)_2\text{SiO}]_4$	D_4	−19.86
$(\text{CH}_3\text{O})_4\text{Si}$	TMOS	−78.22
$(\text{C}_2\text{H}_5\text{O})_4\text{Si}$	TEOS	−81.65
$[(\text{CH}_3)_3\text{SiO}]_4\text{Si}$	M_4Q	+8.62
		−104.08

interchange technique is mostly used. Some useful secondary reference standards are collected in Table 1. Because of their reactivity, they are not universally usable.

There are two special features in measuring silicon NMR. The first concerns the fact that silicon-containing materials such as glass and ceramics constitute a major part of the construction materials of the probehead, resulting in a broad background signal at ca. -110 ppm. There are three ways to alleviate the problem:

- If the signals are narrow, the smallest sweep width possible should be used.
- If there are couplings to protons (or fluorine), population transfer pulse programs such as DEPT or INEPT (see *INEPT*) can be used.
- If the lines are broad, subtract from a blank spectrum obtained under otherwise identical conditions.

The other peculiarity concerns spectra of organosilicon compounds obtained with broadband decoupling of the protons. The nuclear Overhauser effect (NOE) can then lead to null signals, if the $(^{29}\text{Si}, ^1\text{H})$ dipole–dipole contribution T_1^{DD} to the other longitudinal relaxation paths of the silicon is close to 2.52. Because relaxation times depend on the correlation times of a molecule, the signal intensity of a ^{29}Si spectrum with NOE varies with the temperature (see Figure 1). Again there are three methods of working around this situation:

- Doping the sample with a shiftless relaxation reagent, e.g. $\text{Cr}(\text{acac})_3$ (ca. 10^{-2} mol L^{-1}), which also gives shorter relaxation times as a side benefit. There are several disadvantages to this method. The silicon compound can interact strongly with the chromium complex, the purity of the sample is impaired, and population transfer experiments are not effective any more.
- Inverse gated decoupling. Here proton decoupling is only active during acquisition with long waiting times (three to five times the relaxation time T_1) between scans. The advantage of not polluting the sample is offset by an ineffective use of spectrometer time which can be alleviated somewhat by using shorter pulses (40°) and shorter recovery times (20 s).
- Using population transfer pulse programs such as INEPT or DEPT (see *INEPT*).

A review on the use of INEPT and DEPT in silicon NMR has been written by Blinka et al.² Although it appears that population transfer pulse programs provide the best method for obtaining silicon spectra, some of these experiments fail even if there is a known coupling between silicon and hydrogen. One of the reasons may be the short relaxation times of the protons. On the other hand, there may be a sizeable population transfer in the absence of a noticeable coupling between silicon and hydrogen (see Figure 2)

Figure 1 59.625 MHz ^{29}Si spectrum of M_{12}Q_5 [$\text{M} = (\text{CH}_3)_3\text{SiO}_{1/2}$, $\text{Q} = \text{SiO}_{4/2}$] with NOE at different temperatures. The rotation of the M groups is more hindered in the center than at the end of the molecule. Hence the switch from negative to positive signals occurs at higher temperatures

Figure 2 Comparison of the signal intensity of an inverse gated and an INEPT spectrum of the Q-part of M_{10}Q_5 (for M and Q, see Figure 1). The upper trace shows a 59.625 MHz ^{29}Si spectrum without proton decoupling. The $^4J(\text{H,C,Si,O,Si})$ coupling is too small to be measured. Nevertheless a signal enhancement can be reached with a first empirical precession period of 1 s and a second of 0.5 s. The time necessary to obtain the spectra was 30 s in both cases

Figure 3 Chemical shift ranges for typical bonding situations in silicon compounds

3 CHEMICAL SHIFTS

3.1 General Aspects

The greatest spread of chemical shifts occur in Si(II) complexes. The current low-frequency (upfield) limit is that of decamethylsilicocene which has a shift of -577 ppm.³ The largest high-frequency shifts are found for silylene complexes of transition metals, with (1) giving the most positive shift value of $+268.7$ ppm:⁴

where $R = \text{c-C}_6\text{H}_{11}$. The majority of silicon compounds give shifts falling between $+50$ ppm and -200 ppm. The chemical shift ranges for typical silicon compounds are depicted in Figure 3. As is typical for most of the heavier elements, multiple substitution leads to a ‘sagging behavior’ as

demonstrated in Figure 4 for the series $(\text{CH}_3)_{4-n}\text{SiCl}_n$ and *cis*-Os(CO)₄[Si(CH₃)_{3-n}Cl_{*n*}]₂. For chemical shift compilations see Williams and Cargioli⁵ and Marsmann.⁶

3.2 Empirical and Semiempirical Treatment of Silicon Chemical Shifts

The first and simplest approach to the interpretation of silicon chemical shifts was based on the charge on the silicon atom. Thus Ernst et al. observed that silicon chemical shifts follow a parabola if plotted against the sum of the electronegativities of the substituents on the silicon atom. Other examples of charge dependency will be discussed in sections dealing with some selected classes of silicon compounds. A more detailed view was advanced by Radeaglia et al. They used the assumption that of the contributions to the magnetic shielding σ could be subdivided into three components as:

$$\sigma = \sigma_d + \sigma_p + \sigma_n \quad (1)$$

where σ_d represents the diamagnetic component, σ_p the paramagnetic component and σ_n is the influence of neighboring atoms in the molecule, the paramagnetic contribution is responsible for the chemical shift [equation (1)] (see *Chemical Shift Tensors, Shielding: Overview of Theoretical Methods, and Shielding in Small Molecules*). The approximation of

Figure 4 ‘Sagging behavior’ of chemical shifts associated with multiple substitution of a methyl group by chlorine in the series $(\text{CH}_3)_{4-n}\text{SiCl}_n$ (◆) and $\text{cis-Os}(\text{CO})_4(\text{Si}(\text{CH}_3)_{3-n}\text{Cl}_n)_2$ (●). (data from Lickiss⁴)

Jameson and Gutowsky was used considering the 3p orbitals only:

$$\sigma_p = C \langle r^{-3} \rangle P_u \quad (2)$$

where C is a constant including the mean excitation energy ΔE . All magnetic shieldings are calculated relative to the situation σ_{p0} , in which all the electrons are divided evenly between bonding partners. The calculated shielding values may then be written as relative shieldings, σ^* :

$$\sigma^* = \left(\frac{\sigma_p}{\sigma_{p0}} \right) = \frac{P_u \langle r^{-3} \rangle_p}{P_u \langle r^{-3} \rangle_{p0}} = P_u^* \cdot R^* \quad (3)$$

The values of P_u^* and R^* are then calculated using electronegativity values or by CNDO/2. A refinement was made using different bonding angles around the silicon derived from the difference in the electronegativity of ligands around the silicon. An improved fit to the data was obtained by considering the atomic number of the next neighbors on the silicon. For a detailed discussion of this field and references see Marsmann.⁶

Except for a limited set of substituents, for example the halosilanes $\text{SiX}_{4-n}\text{Y}_n$ (X, Y = halogen), linear increments usually do not apply for silicon chemical shifts. Parameters for mutual interactions can then be used if a greater variety of substituents is to be considered. Data are found in Marsmann.⁶ Other substitution parameters will be discussed in the sections below.

Although the silicon chemical shift is mostly determined by elements bonded to the silicon, there are a few general features which influence it, i.e. ring strain, solvent effects, and when the coordination number of the silicon atom differs from the usual value of four. These will be discussed briefly below.

3.2.1 Ring Strain

Incorporating the silicon atom in small rings normally leads to a high-frequency shift compared with the situation in which

Table 2 The Effect of Ring Strain on the Silicon Chemical Shift (δ , ppm)

n	$[(\text{CH}_3)_2\text{Si}]_n$	$(\text{Cl}_2\text{Si})_n$	$[(\text{CH}_3)_2\text{SiO}]_n$
3			−8.93
4	−27.6	5.86	−20.20
5	−42.1	−1.67	−22.80
6	−41.9	−2.54	−22.48
acyclic	−39.2	−1.15	−22.40

Table 3 Chemical Shifts for Some Silacyclopropenes^{3, 6}

R^1	R^2	δ_{Si} (ppm)
CH_3-	$t\text{-C}_4\text{H}_9-$	−87.0
CH_3-	$(\text{CH}_3)_3\text{Si}-$	−88.6
$(\text{CH}_3)_3\text{Si}-$	$t\text{-C}_4\text{H}_9-$	−91.9
$\text{H}(\text{CH}_3)_2\text{Si}-$	$\text{H}(\text{CH}_3)_2\text{Si}-$	−102.1
$(\text{CH}_3)_3\text{Si}-$	$(\text{CH}_3)_3\text{Si}-$	−106.2

the atom is in an open-chain compound. The topic has been fully covered^{3, 6} so that the few examples listed in Table 2 will be sufficient.

Before the value for a silicon in an open chain is attained, there is a small variation towards lower frequency. To date, there are two major exceptions to this rule. The first concerns three-membered rings which give shifts at rather low frequency, as shown by the examples of some silacyclopropenes (2) (Table 3).

In these cases the upfield shift of ca. −90 ppm is attributed to the interaction between the π orbitals on the carbons with d orbitals on the silicon. Sterically demanding ligands on the silicon also lead to a low-frequency shift.³

The other exception is found for the bicyclic silanorbornenes and silanorbornadienes. The shifts of these compounds occur at very high frequencies for a silicon connected to four carbon atoms. A few examples for silanorbornadienes (3) from the work of Sakurai are found in Table 4.

The high-frequency shift of about 80 ppm is attributed to a $\sigma-\pi$ conjugation leading to a positive charge on the silicon. Rings consisting of three silicon atoms show a chemical shift anisotropy similar to a disilene with an $\text{Si}=\text{Si}$ double bond as observed via solid state NMR.⁷

3.2.2 Low Coordination Numbers

By using substituents with a large volume on the silicon, stable compounds in which silicon is linked via a double

Table 4 Silicon Chemical Shifts for the Bridge Silicon Atom in Silanorbornadienes³

	δ (ppm)
$R^1=R^2=CH_3$	76.9
$R^1=CH_3, R^2=Si(CH_3)_3$	82.5
$R^1=CH_3, R^2=Si(CH_3)_2(C_6H_5)$	80.2
$R^1=CH_3, R^2=Si(CH_3)_2Si(CH_3)_3$	85.7
$R^1=R^2=Si(CH_3)_3$	97.7

bond to one of its neighbors can be synthesized. In general, silicon is strongly deshielded when it is involved in a π -bond. Shift values of between 49.9 and 94.7 ppm have been reported for disilenes², but newer data show that 97.8 ppm can be obtained if the substituents around the silicon are of an aliphatic nature.⁸ The assumption of a $p_\pi-p_\pi$ bond is supported by the chemical shift anisotropy data obtained from solid state NMR which demonstrates tensor values comparable with a $p_\pi-p_\pi$ carbon-carbon double bond.² Silenes with a π bond between silicon and carbon give resonances in the range 38–144 ppm.^{9,10} Phosphasilenes with a silicon-phosphorus double bond give signals at an even higher frequency, namely 148–176 ppm.¹¹

3.2.3 Higher Coordination Numbers

Silicon with a coordination number of four still acts as a Lewis acid provided one or more of the substituents are electronegative. Compounds with silicon of higher coordination numbers such as five and six can be formed, with donor atoms, most notably oxygen, nitrogen, and fluorine, leading to a strong low-frequency shift. Reviews have been published elsewhere.^{3,6} However, it is not very easy to establish the degree of higher coordination in solution because equilibria can exist between donor atoms which are attached and those in a free state. For silatranes (1) and related compounds, the observation of $^{29}Si-^{15}N$ coupling (0.20–3.37 Hz) indicates the certainty of a coordination number of five.¹² In addition, the difference between the chemical shifts of silatranes in the solid state and in solution is small (–1.0 to –5.1 ppm).¹³ The additional Si–N bond leads to a shift of between 10–30 ppm to low frequency, as concluded by comparison with the shifts of analogous aminotriethoxysilanes.⁴² A number of complexes of silicon with chelating diols gave shifts of up to –196 ppm,^{3,6} compared with the value of –180 ppm for the mineral thau-masite where the silicon atom is surrounded by six oxygen atoms.¹⁴ This leaves a ca. 100 ppm shift to low frequency as the effect of two extra oxygens in the coordination sphere

of the silicon. Silicon surrounded by five oxygens shows shifts around –120 ppm to –131 ppm, resulting in an additional low-frequency shift of about –50 ppm compared with tetraalkoxysilicates.¹⁵ Solvents with donor atoms can also lead to low-frequency shifts.^{5,16} The chemical shift difference of –24 ppm to –59 ppm occurring in the presence of a donating solvent such as 1-methylimidazole, hexamethylphosphoramide, or dimethylpropyleneurea has been interpreted as being due to the formation of a pentacoordinate complex.¹⁶ Generally, the solvent shift appears to depend on Gutmann's donor number.⁵

The hexafluorosilicate SiF_6^{2-} also exhibits an extremely large low-frequency shift of –191.7 ppm.^{3,6} Shifts of a number of silicon-fluorine anions with silicon in a five-coordinated state have been observed in solution as well as in the solid state. The additional fluorine brings about a low-frequency shift of between –28 ppm and –80 ppm, with the larger effect being for difluorides.^{17–19} The fluxional behavior of these siliconates has been studied mostly by other methods such as ^{19}F NMR, but is also visible in ^{29}Si NMR.

3.3 Chemical Shifts of Selected Classes of Silicon Compounds

3.3.1 The Trimethylsilyl Derivatives

The trimethylsilyl group, $(CH_3)_3Si-$, abbreviated as TMS, is one of the more versatile tools of chemistry. In organic chemistry, one reason for introducing such a moiety into a molecule is to obtain a certain substitution pattern.⁵² Another reason may be to make substances containing labile protons such as –OH or –NH groups easier to handle. Thus, the volatility or solubility in organic solvents is much better for the derivatized compound. The TMS group is also useful for characterization by NMR methods. As several authors have pointed out, most recently Schraml in his review article about tagging with the help of the TMS moiety, the spread of chemical shifts is 0.5 ppm for the proton, 5 ppm for the ^{13}C but ca. 40 ppm for the ^{29}Si resonance of this group. For references consult Schraml.²¹ A chart of the silicon chemical shifts for TMS derivatives is found in Figure 5.

The greatest variation is found for the derivatives of acids. As several authors have shown, in this case the silicon chemical shift of the TMS group depends on the pK value of the parent acid. This has been interpreted as an argument against an appreciable $p_\pi-d_\pi$ contribution to the Si–O bond. Furthermore, the chemical shifts of trimethylsilylalkoxides correlate with the charge at the oxygen and the polar substituent constant σ^* . As can be deduced from Figure 5, the chemical shifts of the different types of TMS alkoxides overlap somewhat, and this could be a problem if the TMS derivatives are to be used to characterize polyols, such as carbohydrates and other natural products where the resonances of the trimethylsiloxy groups appear over a very narrow region.

**Figure 5** Chemical shift ranges of the trimethylsilyloxy group (reproduced with permission of Wiley from Schraml²¹)

Figure 6 Partial H,H-, H,C-, and H,Si-COSY spectra of the trimethylsiloxy derivative of methyl 2-(β -D-xylopyranosyl)- β -D-xylopyranoside (reproduced with permission of Wiley from Schraml²¹)

With CDCl_3 as solvent, the shifts of the $(\text{CH}_3)_3\text{SiX}$ group ($\text{X} = \text{O}, \text{N}$) depend slightly on the concentration of the solute, and so Schraml proposed a ‘standard condition’ in order to improve the reproducibility of the shift data. Thus if the ^{13}C resonance of CDCl_3 is set equal to 76.99 ppm, the ^{13}C resonance of $[(\text{CH}_3)_3\text{Si}]_2\text{O}$ (M_2) used as a secondary standard should be 2.48 ± 0.02 ppm. Otherwise, the sample should be diluted further with CDCl_3 .

Several procedures have been suggested to give additional information needed to make such an assignment. Most of the techniques have been developed by the groups of Harris and Schraml. One of the simpler, but still difficult, methods involves the selective decoupling of the methyl protons of the TMS group. The only splittings left then arise from the $(\text{CH}_3)_3\text{SiOCH}_n$ —part of the molecule. A triplet then stems from a primary, a doublet from a secondary, and a singlet from a tertiary alkoxy group. Selective deuteration can be used to distinguish between resonances from different locations in the molecule as demonstrated by Harris.

INEPT experiments with selective excitation of proton resonances also provide another valuable tool. By combining H,H-, H,C-, and H,Si- two-dimensional COSY, the task of assigning can be greatly simplified. An example is found in Figure 6. Additivity rules exist to connect chemical shifts to structural models of steroid alcohols and carbohydrates (pentoses). For data, Schraml²¹ should be consulted.

While trimethylsilylated enols show marked differences for *E* and *Z* isomers, the shifts of aryloxy derivatives are far more predictable. The shift value for trimethylsiloxyphenols of the type $X-C_6H_4-OSi(CH_3)_3$ depends on the Hammett σ parameter, but the relative position of *X* is much less

Figure 7 Structural diagram for the building units in polysiloxanes

influential. The shift of the TMS–O group is almost identical for X when in the *meta* and *para* positions. An *ortho* substitution shifts the resonance ca. 1.5 ppm to high frequency if X contains lone pairs and only a little if X has none. The temperature dependence of the shifts (ca. 1 ppm for a temperature difference of 150 °C) has been interpreted as being caused by the silicon of the TMS–O group being perpendicular to the phenyl ring in the ground state and rotated more to the plane of the ring at higher temperatures. TMS–O derivatives of multiply substituted phenols have been studied as model compounds for lignins and coals. The data for a number of potential structural components for trimethylsilylated lignins have been collected.²¹

Trimethylsilylation as a means of characterizing silicates was originally suggested by Lentz.²⁰ Although the silicon shifts of the silicate skeleton are used primarily for this purpose, the region 8.35–13.65 ppm is typical for TMS–O groups connected to a silicic acid skeleton.²²

3.3.2 Oligomeric and Polymeric Siloxanes

One of the first uses of silicon NMR was its application to siloxane polymers. Although it is sometimes possible to recognize and isolate individual molecules, the main aim is to dissect the molecules into building units (see Figure 7). To distinguish between building units with different substituents at the silicon, a short notation for the substituent is added as a superscript. As the methyl group is thought to be the normal case, it is not considered in the notation. The chemical shift regions of such building units are collected in Figure 8. The main difference between the building units is the number of oxygen atoms connected to a silicon atom. Except for the M group, the exchange of an R substituent for oxygen leads to a low-frequency shift. The chemical shifts of the building units are sensitive to neighbor effects in the chain structure, thus revealing the microstructure of the polymers. This was demonstrated, for example, by Harris and Kimber, who deduced the triad and pentad structures of a mixed oligomer consisting of D and D^H groups,²³ and by Engelhardt and Jancke for the system D and D^{Ph}.²⁴ As stated above, the chemical shifts of all building groups are modified by ring strain.

The analysis of the silicic acid anions in aqueous solutions is a formidable feat. A status report on the different methods to achieve this has been published by Hoebbel and Ebert.²⁵ Fast

Figure 8 Silicon chemical shift regions of building units of polysiloxanes (reproduced with permission of Wiley from Williams³)

Figure 9 Structural diagrams and shift values of silicate anions identified in aqueous solution (relative to the resonance of the monosilicate δ_{TMS} ca. -71.3 ppm)

and slow hydrolysis condensation reactions between silicate anions and protonation equilibria exist depending on the pH and silicate concentration of the solution.^{26–28} This makes assignments beyond the basic principles difficult (see Table 5). One way out of this dilemma has been the use of ²⁹Si-enriched material. This opens the opportunity to undertake ²⁹Si, ²⁹Si-COSY experiments or classical assignments by the selective decoupling technique. Some of the anions identified in this way are collected in Figure 9.^{29–31}

Because the chemical shifts of the anions depend on the pH value, it is common practice to use the resonance of the monomeric species SiO_4^{4-} as a secondary standard, which from its own shift variation with pH and concentration makes it easier to track the signals of the other anions. A rough conversion to the shift scale based on TMS can be obtained by adding -71.3 ppm. An inspection of Figure 9 reveals the following:

- The shift difference of the building units is smaller than in the case of other oligomeric siloxanes.
- Condensed ring structures are common.

Figure 10 Comparison of chemical shifts relative to the neso group of silicate anions with the corresponding silicic acid derivatives (reproduced with permission of Springer Verlag from Bertling and Marsmann³³)

- (c) Shift variations caused by ring strain can make resonances from the Q^n building unit appear in the same place as those of Q^{n-1} .

The chemical shifts of silicic acid esters are closely related to those of the silicic acid anions and this can help in assignment (Figure 10). The shift regions for the acyclic esters are given in Table 5. The exceptions are the TMS esters which are often used for the characterization of silicates. Here ring strain effects are more prominent and so a shift correlation with other species is not observed.²²

3.3.3 Oligomeric and Polymeric Silanes

This topic has been discussed by Williams³ and the pertinent references should be looked up there. The chemical shift ranges for the building units of some oligomeric silanes are collected in Table 6.

The skeleton of these compounds is similar to that of alkanes. Therefore, models as used by Grant and Paul for the ^{13}C resonance have been applied to rationalize the shifts of this class of compounds. Hahn fitted the empirical equation:

$$\delta_{Si} = -96.02 - 2.43a - 3.73a^2 + Bb + C \quad (4)$$

where -96.02 ppm is the idealized shift of the monosilane SiH_4 , a is the number of silicon atoms in the α position, b the number of silicon atoms in the β position, and B and C are incremental chemical shifts due to β - and γ -positioned silicon atoms. West and Stanislawski used a similar approach [equation (5)] to explain the shifts of oligomeric permethylsilanes:

$$\delta_{\text{Si}(k)} = B + \Sigma A_l n_{kl} \quad (5)$$

where the constant B is 8.5 ppm and A_I represents the influence of silicon atoms in the α (-28.5 ± 0.10 ppm), β ($+3.9 \pm 0.05$ ppm), γ ($+1.2 \pm 0.09$ ppm), and δ positions ($+0.2 \pm 0.01$ ppm) relative to the silicon atom considered, and n_{kl} the incidence of A_I . Substituent parameters for fluorine or chlorine could also be calculated. The model was not successful for cyclic silanes and quaternary silicon atoms. This

Table 5 Silicon Chemical Shifts^a of Building Units of Silicic Acid Anions and Derivatives

	Neso group	End group	Middle group	Branching group

OCH ₃	−172.2

is not surprising considering the spread of shifts for quaternary silicon atoms in silanes and their sensitivity to substitution β to the central silicon as the few data listed in Table 7 show. The review also cites a number of studies on substituted di- and trisilanes.³

3.3.4 Transition Metal Complexes

The data for a number of transition metal complexes are collected in some reviews.^{3,4,6,34} There is a large variety of bonding situations for the silicon atom leading to a large spread of chemical shifts. The first variable is the kind of metal involved. Complexes studied so far have central atoms belonging to Groups 6 to 12 of the Periodic Table, with iron as the most often used. Although there are still not enough data known to explain the shifts of silicon bonded to transition metals, a few trends emerge. There seems to be a low-frequency shift for a given silicon-containing ligand in going to a heavier homologous transition metal. The ‘sagging pattern’ found in ordinary silicon compounds is also encountered for such complexes³⁴ (see, for example, Figure 4). A very useful concept was suggested by Pannell and Bassindale for more conventional complexes where the silicon is linked via a single bond to the metal.³⁵ In Table 8 the chemical shift of a central silicon atom is compared with the shift of the silicon where the metal is replaced by a methyl group. A high-frequency shift of up to +40 ppm is observed if the metal is Fe or Ru, but a low-frequency shift of −13 to −39 ppm is obtained if the metal is Re.³⁶ Somewhat larger values are found if the chemical shift difference is that between the shifts of silicon in the complex and in the corresponding silane.³⁷ Silicon in

Table 8 Silicon Shift Differences^d Δ[δ(LM²⁹Si) − δ(CH₃²⁹Si)] for Some Transition Metal Complexes

^dIn ppm.^eL = CO, P(C₆H₅)₃, R = methylsilanes.³⁵^fR = methylsilanes.³⁶^gΔ[δ(LM²⁹Si) − δ(H²⁹Si)].³⁷

a β position to the metal experiences a less pronounced low frequency shift of up to 20 ppm. Silicon in the γ position is only shifted by a small amount.^{35–37} In π complexes where the silicon is next to the carbon–carbon double bond, the shift difference to the free ligand is between −2 and +21 ppm.³⁸

Extreme high-frequency shifts are experienced by silicon atoms in nonclassical complexes containing silylenes as ligands.⁴ If the silylene ligand is either doubly bonded to the metal or is attached via a single bond to two metals, then shifts between 230 and 269 ppm are observed. If the complex is stabilized by donor molecules at the silicon, then the shifts are found in the region between 58 and 127 ppm.

3.3.5 Miscellaneous

Silazanes have structures similar to siloxanes and can be rationalized by the same principles, but the spread of chemical shifts is smaller. The total region extends from −62 ppm to +18 ppm.⁶ The same is true for carbosilanes where resonances are found for silicon connected to four carbons of between −4 ppm and +20 ppm.⁶ A new report has appeared for silthianes.³⁹ Generally, the shifts are placed to higher frequencies as compared to siloxanes. For the other compounds, general collections of silicon chemical shifts should be consulted.^{5,6}

4 COUPLING CONSTANTS

All magnetic nuclei in a molecule interact and the resulting splitting gives rise to typical patterns. Two cases can be distinguished:

(a) Coupling with abundant isotopes such as ^1H , ^{19}F , or ^{31}P gives rise to well-known splitting patterns in ^{29}Si spectra. Couplings with quadrupolar nuclei such as the isotopes of chlorine are usually not observed, but can lead to broad lines.

(b) Coupling with other rare spins such as ^{29}Si itself or ^{13}C leads to small satellite lines on each side of the main line.

The amount of data available is governed by the fact that ^1H – ^{29}Si couplings are easily obtained and the discussion of these predate the advent of silicon NMR itself. Theoretical approaches and data for couplings concerning silicon are summarized in Marsmann⁶ and Schraml and Bellama⁴⁰ and the arguments presented here are taken from these sources. Of the three possible pathways for transmitting information about the other spins to silicon, the Fermi contact term is assumed to be the most effective (see **Indirect Coupling: Semiempirical Calculations**). As consequences of this, the sign of the coupling constants for $^1J(\text{Si},\text{H})$ is negative because of the negative gyromagnetic ratio of the isotope ^{29}Si . The magnitude of the couplings depends on the s orbital density between silicon and the other coupling nucleus and an average excitation energy ΔE . The latter quantity is difficult to assess. Therefore semiquantitative and empirical relationships have been found by several authors—mostly for $^1J(\text{Si},\text{H})$ and $^1J(\text{Si},\text{C})$. A few examples (J values in Hz) are:

$$^1J(\text{Si},\text{H}) = 725\alpha_{\text{Si}}^2 + 15.9 \quad (6)$$

$$^1J(\text{Si},\text{H}) = 969.7\alpha_{\text{Si}}^2 + 5.9N_{\text{P}} - 41.0 \quad (7)$$

$$^1J(\text{Si},\text{H}) = 810\alpha_{\text{Si}}^2 + 4.30N_{\text{P}} - 1.40N_{\text{Me}} \quad (8)$$

for $\text{H}_n\text{SiR}_{4-n}$ ($\text{R} = \text{CH}_3$, C_6H_5 ; $n = 1-4$)

$$^1J(\text{Si},\text{C}) = 555.4\alpha_{\text{C}}^2\alpha_{\text{Si}}^2 + 18.2 \quad (9)$$

$$^1J(\text{Si},\text{C}) = -1227.7P_{\text{SiSiC}}^2 + 26.0 \quad (10)$$

where α_{E}^2 is the square of the s character of the hybrid used for bonding onto element E, P_{SiSiC} is the bond order matrix element pertaining to the SiC bond, and N_{P} is the number of phenyl and N_{Me} the number of methyl groups bonded to the silicon atom.³ A more complete collection is published elsewhere.^{6,40} On a purely empirical basis, the magnitude of the coupling constant depends on the electronegativity of the substituents, but is nonlinear. Some quadratic relationships have been suggested on the basis of pairwise interaction parameters (Malinowski) or effective electronegativities (Jensen). The quantity $^1J(\text{Si},\text{H})$ can also be connected to other properties of a molecule, e.g. the H–Si, the Si–Si stretching frequencies (Hengge), or the Hammett–Taft σ^* term (Nagai).

The ranges of some coupling constants involving silicon are found in Table 9. The sign of the coupling constants over one bond is usually negative because of the negative magnetogyric ratio of the ^{29}Si . Exceptions are found if the silicon is connected to an element with tightly bonded s electrons, e.g. ^{19}F or ^{31}P .

Table 9 Ranges of Some Coupling Constants Involving Silicon

Type	Sign	Values (Hz)
$^1J(\text{Si},\text{H})$	–	420–75
$^2J(\text{Si},\text{CH}_3)$	+	10–3
$^2J(\text{Si},\text{XH})$	±	13–1
$^3J(\text{SiH})$		8–1
$^1J(\text{Si},\text{F})$	+	488–108
$^2J(\text{Si},\text{F})$	–	91–17
$^3J(\text{Si},\text{F})$	±	16–2
$^1J(\text{P},\text{Si})$	+	256–16
$^2J(\text{P},\text{Si})$	±	44–0.7
$^1J(\text{Si},\text{C})$	–	113–37
$^2J(\text{Si},\text{C})$	+	18–4
$^1J(\text{Si},\text{Si})$		186–23
$^2J(\text{Si},\text{Si})$		24–0.7

4.1 Silicon–Hydrogen Couplings

For the one bond hydrogen–silicon coupling a rough correlation exists with the electronegativity of the other bonding partners to the silicon. This is an application of Bent's rule that atomic s character concentrates in orbitals directed toward electropositive substituents. The exception is $\text{H}_2\text{Si}[\text{Mn}(\text{CO})_5]_2 \cdot 4\text{py}$ where the extreme value of 420 Hz is observed. Hence the value of -381.7 Hz for HSiF_3 is a better upper working limit for $^1J(\text{Si},\text{H})$. H_3SiK [$^1J(\text{Si},\text{H}) = 74.8$ Hz] gives the lowest value in concordance with the low electronegativity of potassium. The coupling of silicon with the hydrogen of a methyl group runs from 6.0 Hz to 9.5 Hz in most cases. Exceptions are found if the silicon is bound to an alkali metal such as Li, e.g. $(\text{CH}_3)_3\text{SiLi}$, $^2J(\text{Si},\text{CH}_3) = 2.8/3.5$ Hz. The value between 20 and 69 Hz found for $^2J(\text{Mn},\text{Si},\text{H})$ has been thought to arise from a direct bonding interaction between silicon and hydrogen.^{37,41}

4.2 Silicon–Fluorine Couplings

The value of $^1J(\text{Si},\text{F})$ for fourfold coordinated silicon lies in the range 167–488 Hz. The lower limit is found in perfluorosilanes and the high value for the cyclic $\text{CH}_2\text{CH}_2\text{SiF}_2\text{SiF}_2$.⁴⁰ Higher coordination numbers lead to lower values, e.g. 131–300 Hz for five-coordinated silicon^{6,17,18} and 108–182 Hz for silicon with a coordination number of six.⁶

4.3 Silicon–Phosphorus Couplings

One bond couplings in silylphosphines can be calculated by the empirical equation:

$$^1J(\text{P},\text{Si}) = 26.3 + 8u + 5v - Zw \quad (11)$$

where 26.3 is the value for the reference compound (H_3SiPH_2) with u the number of silyl, v the number of methyl groups substituting P–H bonds, and w the number of methyl groups substituting Si–H bonds. The quantity Z is an empirical factor with a value of 3.3–5. Coupling across a silicon–phosphorus double bond gives splittings of 149–155 Hz.¹¹ The two bond coupling over nitrogen enables the bonding situations between

P=N–Si and P–N–Si to be distinguished. Very low values have been found if the couplings go over triply linked nitrogen, but values of 8–42 Hz are typical for a sp^2 -hybridized nitrogen between silicon and phosphorus.⁶

4.4 Silicon–Carbon and Silicon–Silicon Couplings

The range for the splittings of the satellites in a ^{29}Si spectrum due to the presence of a ^{13}C one bond away is 44–107 Hz where electronegative substituents at the silicon and sp^2 -hybridized carbon favor the higher values. A coupling constant of 83.7 Hz has been reported for an Si–C double bond.⁴² The silicon–silicon coupling across a double bond has been measured as 155–158 Hz⁴³ and is enhanced compared with values of around 85 Hz for arylsilanes.⁴⁴ Little is known about higher bond Si–Si couplings. In stress-free linear and cyclic silanes, $^2J(\text{Si},\text{Si},\text{Si})$ is found in the range 3–13 Hz, but in polycyclic silanes values of 14–24 Hz can be observed.^{45,46} Because the magnitude of $^1J(\text{Si},\text{Si})$ in polycyclic silane rings is reduced, both types cannot be distinguished easily.⁴⁵ The value of $^2J(\text{Si},\text{O},\text{Si})$ is generally very small with values of 3.6–9.8 being observed in silicate anions. Trimethylsilyl silicates gave slightly larger values of 6.7–13.5 Hz for the couplings between the silicon atoms of the skeleton.²²

5 SPIN–LATTICE RELAXATION

As an isotope with a spin of $\frac{1}{2}$, ^{29}Si has five pathways to dissipate to the surroundings (lattice) any excess energy stored in its excited Zeemann level. The mechanisms for these relaxation processes are basically the same as for excitation, i.e. fluctuating magnetic fields. Such fluctuating magnetic fields can arise from other magnetic dipoles, T_1^{DD} , interaction of the spin with the molecular rotation, T_1^{SR} , the chemical shift anisotropy, T_1^{CSA} , scalar interactions, T_1^{SC} , and the presence of unpaired electrons in the sample, T_1^{E} . The total relaxation is then the reciprocal sum of all these components [equation (12)]:

$$\frac{1}{T_1} = \frac{1}{T_1^{\text{DD}}} + \frac{1}{T_1^{\text{SR}}} + \frac{1}{T_1^{\text{CSA}}} + \frac{1}{T_1^{\text{SC}}} + \frac{1}{T_1^{\text{E}}} \quad (12)$$

Results obtained up to 1981 have been summarized by Marsmann⁶ and if not indicated otherwise the following discussion is based on the references cited there. In the absence of substances with unpaired electrons, Levy has shown that the dipole–dipole and the spin–rotation mechanisms are the most efficient contributions to the total ^{29}Si relaxation. The value of T_1^{DD} is usually dominated by interaction with the magnetic moments of the protons:

$$\frac{1}{T_1^{\text{DD}}} = h^2 \tau_c \sum \gamma_{\text{H}}^2 \gamma_{\text{Si}}^2 r_{\text{SiH}}^{-6} \quad (13)$$

The silicon–hydrogen bond distance is ≈ 148 pm so the effectiveness is only 10% compared with the same situation with carbon. Hence hydrogens further away, both intra- as well as intermolecular, are also effective. This is important because in the usual organosilicon compounds the hydrogen is not bonded directly to the silicon but is found in a side chain.

Relaxation times are also dependent on the dilution of the silicon compound and on the concentration of proton-carrying

molecules (solvents). The molecular correlation time τ_c in equation (13) describes the rotational tumbling motion. Very often a molecule cannot be considered as rigid, so an effective correlation time τ_c^{eff} is used. The motions of a molecule depend on the temperature of the sample and Arrhenius-type relationships between temperature and T_1^{DD} are observed. The share of the dipole–dipole term on the total relaxation time can be obtained from the nuclear Overhauser effect (NOE) which is obtained by the change of intensity by decoupling another nucleus, usually protons:

$$\begin{aligned} \text{NOE} &= \frac{\text{signal intensity with irradiation of protons}}{\text{signal intensity without irradiation}} \\ &= 1 + \frac{\gamma_{\text{H}} \cdot T_1}{\gamma_{\text{Si}} T_1^{\text{DD}}} \end{aligned} \quad (14)$$

If the silicon nucleus relaxes exclusively via T_1^{DD} then the NOE becomes -1.52 . The NOE enhancement factor η is calculated as:

$$\text{NOE} = 1 + \eta \quad (15)$$

with $\eta_0 = -2.52$ being the NOE enhancement factor for exclusive relaxation by dipole–dipole interaction. For the normal case where dipole–dipole relaxation is the sole mechanism, its share is given by:

$$T_1^{\text{DD}} = -\frac{2.52 T_1}{\eta} \quad (16)$$

If $\eta = -1$ then a null signal in the ^{29}Si spectrum is the consequence. (See also *Nuclear Overhauser Effect*.)

The spin–rotation interaction is the other effective relaxation mechanism. The rotation of a molecule or a part of it generates a ring current via the electrons connected to it. Changes in the rotational speed produce the fluctuating magnetic fields necessary for the relaxation process. If the molecule moves isotropically, the spin–rotation relaxation time is given by:

$$\frac{1}{T_1^{\text{SR}}} = \frac{2\pi I k T}{h^2} \frac{2C_{\perp}^2 + C_{\parallel}^2}{3} \tau_j \quad (17)$$

In equation (17), τ_j is the angular momentum correlation time. If the molecular reorientation occurs by small-step diffusion, then the Hubbard relationship applies:

$$\tau_c \tau_j = \frac{I}{6kT} \quad (18)$$

The practical application is that at high temperatures the relaxation is governed by the spin–rotation process and at lower temperatures by the dipole–dipole interaction, and that there is a border region where T_1 reaches a maximum value (see Figure 11). The components of the spin–rotation interaction tensor $\mathbf{C}$ are difficult to determine, but contain information about the paramagnetic term of the chemical shift σ_{p} .^{6,47} (See also *Spin–Rotation Relaxation Theory*.)

The effect of unpaired electrons can be used very effectively to shorten the total relaxation time and to suppress the NOE, because the main relaxation path no longer goes through the dipole–dipole interaction. The addition of $\text{Cr}(\text{acac})_3$ in ca. 10^{-2} molar concentration was suggested by Levy et al. to bring relaxation times down below 10 s. In addition, the presence of molecular oxygen in a sample shortens the relaxation times.

Figure 11 ^{29}Si spin-lattice relaxation in tetramethylsilane: (●) T_1^{DD} , (▲) T_1^{SR} (assumes $T_1^{\text{CSA}} \gg T_1^{\text{DD}}$) (reproduced with permission of the American Chemical Society from Levy et al.⁴⁸)

Table 10 Typical Relaxation Times for ^{29}Si at Room Temperature^{6, 49, 50}

Compound	T_1	T_1^{DD}	T_1^{other}
$(\text{CH}_3)_3\text{SiH}$	15.9	190	175
$(\text{C}_6\text{H}_5)_3\text{SiH}$	12.0	12.5	275
<i>Siloxanes</i>			
M	35–52	150–320	40–61
D in chains	54–67	73–247	69–266
D in rings	80–100	102–183	142–820
D^{H} in chains	30–46		
Methyl silicates	73–205	320–503	
Chlorosiloxanes	53–352		
<i>Silicates in aqueous solution</i>			
Q^0	0.3–3.8		
Q^1	1.4–2.7		
Q^2	1.4–4.6		
$(\text{Q}^3)_8$	9.8	11.8	

The value of T_1^{E} was calculated to be around 37 s for an oxygen pressure of 1 atm.⁴⁸

An inspection of the relaxation data listed in Table 10 shows that the principal pathway for dissipating energy from the spin system is the spin-rotation mechanism, because it is safe to assume that T_1^{other} consists almost exclusively of T_1^{SR} . Exceptions occur if the segmental motion in larger molecules is constricted, as in the case of small siloxane rings, or the silicon bears one or more directly connected hydrogens. The short relaxation times of silicate anions in aqueous solution have attracted much attention. An explanation may be relaxation by unpaired electrons from transition metal ions leached from the glass of the NMR tube. The equilibria between different silicate ions or protonated forms may be another factor.^{26–28, 51}

The longitudinal relaxation times are usually determined by inversion-recovery pulse programs modified to avoid null signals which are possible via the negative gyromagnetic ratio of ^{29}Si as suggested by Levy et al. Harris has proposed a pulse cycle using a null signal to obtain the relaxation times.⁶

1 INTRODUCTION

In order to avoid duplication with earlier reviews, I will cover only the main areas of activities during the last decade or so. This explains why fundamental aspects such as the super-Lorentzian lineshape outside of extreme narrowing—biexponential relaxation is now accessible by multiple quantum methods¹ and lineshapes for exchange kinetics are available;² direct determination of the attendant dynamic frequency shift is feasible³ (but will not be repeated here), and the question of why applications such as studies of ion pairing as for instance in McCormick et al.,⁴ Iida and Hata,⁵—will not be found here. Neither shall I cover the classic demonstration of the existence of the sodium anion, which is dealt with at proper length elsewhere in this Encyclopedia. In addition, space restriction does not allow coverage of applications to liquid crystalline mesophases whose heyday is now past its prime despite some excellent studies^{6–8} and extensions to suspensions of clay platelets.⁹ Likewise, the application to micelles¹⁰—a field in itself, thriving because of relevance to the industry of detergents—will not be further detailed.^{11,12} I will just mention the potentially useful technique of spin- $\frac{3}{2}$ relaxation in the doubly rotating tilted frame.¹³

2 SODIUM COORDINATION AND PREFERENTIAL SOLVATION

The sodium anion Na^- with its filled 3s electronic levels has a remarkably invariant chemical shift of -62 ± 1 ppm.^{14–16} By contrast, the Na^+ cation has a chemical shift ranging from -52 ppm for the tetraphenylborate salt in the solid state¹⁷ to solution values ranging between 0 and $+60$ ppm, in proportion to donation from counteranion and solvent lone pairs on to the sodium 3p orbitals.¹⁸ The calculated changes in nuclear shielding constants of Na^- (gas) with respect to Na^+ (gas)

amount to shielding by only 7.7 ppm for full addition of two electrons to gaseous Na^+ (gas) to form Na^- (gas).¹⁹ In the solid state, chemical shifts depend on ligand type (water ≈ 0 , hydroxy ≈ -2 , carbonyl -8 to -12 , diethyl ether -10 , ionophores -15 to -25 ppm). Some ionophore complexes (monensin, tetranactin) display near-identical chemical shifts in the solid state and in solution. Other complexes, when solvent molecules are able to get to the encapsulated sodium cation, show substantial (10–20 ppm) downfield shifts.²⁰

We now select for praise a handsome study using magic angle spinning of several homoionic Llano vermiculites.²¹ These are swelling clays. Each state of hydration goes with a specific value of the chemical shift, more and more to high frequency (downfield) as the number of molecules in the interlayer increases. For ^{23}Na , ^{111}Cd , and ^{133}Cs a reduced isotropic chemical shift is defined as $\delta_{\text{iso}} \times \nu_0$, where ν_0 is the Larmor frequency. This chemical shift δ is determined to first approximation by the oxygen ligands. Their donation to the empty orbitals of the cation is in proportion to their ionization enthalpy I . In the second approximation, the chemical shift depends also on the configuration of the M ligands within the N sites available to the cation. Assuming that δ/I is like the partial potential of a configurational shielding energy, Fripiat predicts that $\delta/I \propto \ln(M)/(N - M)$, as it indeed does handsomely.

Sodium-23 NMR is very good at detecting mixed solvates with their nonvanishing electrostatic field gradient leading to marked increases in linewidth. Since each discrete solvate has a characteristic chemical shift and linewidth, even under the prevailing situation of fast ligand exchange, one can often obtain and offer the full story of preferential solvation over the whole range of composition for a binary solvent mixture. It includes solvation numbers, the rate constants and the thermodynamic equilibrium constants for interconversion between the coexisting complexes, and determination of the associative or dissociative character of ligand exchange.²²

3 INCLUSION COMPLEXES

Shchori et al. kicked off the kinetics of Na^+ exchange in 1971.²³ Decomplexation of Na^+ from its complex with dibenzo-18-crown-6 provided a favorable case, since the rate of chemical exchange is of the same magnitude as relaxation rates. In these initial studies,²⁴ the chemical shift difference between the free and bound states was negligible. If conversely there exists such a chemical shift difference, the transverse relaxation rate exceeds the longitudinal relaxation rate because of exchange broadening. In this latter case, under the appropriate (solvent, temperature) conditions one is looking only at the resonance for free sodium ions broadened by exchange with the underlying signal for bound sodium ions, whose intensity is too low for direct detection. A number of studies have followed this scheme.^{25–43} Some address the mechanistic question of whether Na^+ exchange obeys a unimolecular ($\text{Na}^+, \text{C} \rightarrow \text{Na}^+ + \text{C}$) dissociative or a bimolecular $^*\text{Na}^+ + (\text{Na}^+, \text{C}) \rightarrow \text{Na}^+ + (^*\text{Na}^+, \text{C})$ associative mechanism.⁴⁴

Alternatively, separate ^{23}Na resonances for free and complexed states have been observed for encapsulation by cryptands,^{45–48} or with the tetraphenylborate counterion in

solvent-separated ion pairs. The reader is reminded of the distinction between tight ion pairs in which anion and cation are nearest neighbors and loose ion pairs in which at least one solvent molecule gets in between the ionic partners.

4 POLYELECTROLYTES

Exploration of the area is to be credited to the group in Lund. Early on, they examined changes in quadrupolar relaxation with concentration of a natural or synthetic polyelectrolyte.^{49,50} Synthetic polyelectrolytes such as poly(acrylic acid) and poly(methacrylic acid) and also natural polyelectrolytes such as mucopolysaccharides were studied.^{51,52} Before reviewing these and other contributions, we have to introduce the key relevant ideas. A conceptually and operationally useful distinction contrasts site binding (i.e. tight ion pairs) and atmospheric condensation (loose ion pairs). The former is describable by complex formation, with the attendant thermodynamic equilibrium constant. The latter, not amenable to such a description, is the generalized attraction of the counterions into the electrostatic potential well from the polyelectrolyte, so as to screen from one another the amassed charges of like sign. The polyion is characterized by high linear charge density. When it exceeds a critical value, then accumulation of the counterions occurs. Electrostatic theories provide models for atmospheric condensation. The crudest variety is an all-or-nothing two-state model devised by Manning,⁵³ that accounts nicely for condensation occurring as soon as the counterion concentration reaches a critical value set by the linear charge density on the polyelectrolyte. However most authors now perform a more accurate Poisson–Boltzmann calculation of the mole fraction of atmospheric ions,⁵⁴ to apply it for instance to the ²³Na NMR of poly(styrene sulfonate)⁵⁵ or to condensation of sodium ions around micelles.⁵⁶

The Manning model, useful as a first approximation, defines a reduced linear charge density ξ . Its critical value is unity for a univalent counterion such as Na⁺. The corresponding critical distance d_c between the adjoining like charges on the polymer is 7.1 Å in water at 25 °C, and ξ is simply the ratio to d_c of the mean actual distance between adjacent charges, projected onto the cylindrical axis of the polyanion. As soon as ξ reaches unity sodium counterions condense into the atmosphere around the polyanion. The charge fraction f of nonneutralized negative charges on the polyanion is unity whenever $\xi < 1$ and with $(\xi)^{-1}$ otherwise. For instance, in the interaction of Na⁺ with polyacrylic acid, no condensation occurs at $\xi = 0.8$ but is observed at $\xi = 1.1$.⁵⁷

Monitoring dispersion of ²³Na longitudinal and transverse relaxations at nominal frequencies between 8 and 64 MHz for sodium ions in poly(methacrylic acid) solutions provides in an assumption-free manner the relevant spectral densities; the procedure indicates that a simple two-state model, consisting of a simple Lorentzian density for bound ions and a white noise density for the free ions in the bulk solution, is inadequate.⁵⁸ In general, sodium cations interacting with polyanions lead to relaxation rates outside the extreme narrowing limit.^{59,60} A control experiment, i.e. shielding the sodium ions with a cage-like ligand such as the [2.2.2]cryptand confirms this finding. The sodium NMR becomes immune to the proximity of the polyelectrolyte when ²³Na relaxation is dominated by the electrostatic field gradient from the coordinated ligand.⁶¹

The general situation described by many authors is a small degree of specific site binding coexisting with predominant nonspecific atmospheric condensation. Very often, the correlation time of bound sodium ions is sufficiently long that magnetization decay acquires biexponential character, as displayed in super-Lorentzian lineshapes. This served to characterize the state of sodium ions in hydrocolloid systems,⁶² in aqueous solutions of sodium pectate and polyuronates,⁶³ and a solvent relaxation NMR bound-fraction determination for sodium poly(styrene sulfonate) at the solid–solution interface.⁶⁴ An early example will give the flavor of these studies. Glycosaminoglycans are carbohydrate biopolymers occurring at neuronal synapses, in the extracellular volume of connective tissues, etc. Examples are chondroitin sulfate and dermatan sulfate with one ionizable group alternatively –OSO₃[–] and –COO[–] on each monosaccharide unit, and hyaluronic acid with a carboxylate –COO[–] group on every second monosaccharide unit. The transverse relaxation rate R_2 changes in sigmoidal manner with the degree of neutralization α . Comparing longitudinal and transverse relaxation rates yields the product $p_B \chi^2$, where p_B is the mole fraction of bound Na⁺ ions and χ the quadrupolar coupling constant. This product undergoes a sharp increase in the range $\alpha = 0.6$ – 0.9 . In this range, χ is essentially independent of α , with a value of about 0.15 MHz consistent only with a full hydration shell and therefore with atmospheric condensation rather than site binding.⁶⁵

The late Ed Gabbay pioneered the use of ²³Na NMR to examine the influence of DNA on counterions coexisting in solution. The DNA polyanion increases markedly the relaxation rates of the ²³Na⁺ counterions. By measuring longitudinal relaxation at three distinct frequencies (4.3, 8.15, 15.7 MHz), the authors determined a reorientational correlation time τ_c of 5.5 ns. The concentration dependence gave a limiting relaxation rate in the bound state of 170 Hz, that translated into a quadrupolar coupling constant $\chi = 0.1$ MHz. Such a low value rules out site binding and is nicely consistent with atmospheric condensation.⁶⁶ It remained to be shown that the linear dependence of the relaxation rate enhancement with DNA content is accountable by electrostatic theory, which the Madison group proceeded to do. One of the tenets of Manning's model is the invariance of the neutralized fraction of the DNA polyanionic charge; Anderson, Record, and Hart successfully addressed this issue.⁶⁷ Work continued at a steady pace.^{68–71} In 1984, a study was made on three synthetic polynucleotides and on DNAs from four different species, calf thymus, *Clostridium perfringens*, *Escherichia coli*, and *Micrococcus lysodeikticus*: the ²³Na spectra (at 4.7 T) were uniformly non-Lorentzian. All of the sodium correlation times continued to be in the range of nanoseconds, and the Madison group concluded on a dominance of the relaxation process by the radial translational diffusion of sodium ions away from the nucleic acid semirigid rod.⁷² A number of interesting studies followed.^{73–79}

More recently, increased sophistication came into play, and ²³Na NMR was used to monitor intercalation of various drugs in the DNA double helix. The basic idea is very simple: intercalation extends the helix whereby the mean phosphate-to-phosphate distance increases. The overall decrease of the DNA charge density should and does lead to a lesser degree of atmospheric condensation for the counterions.^{80–82} In this manner intercalation of 9-aminoacridine has been studied.⁸³ Intercalation mainly affects the part of the spectral density

function describing the contribution of the fast modulations to the relaxation. These fast motions may be ascribed to anisotropic fluctuations in the symmetry of the Na^+ hydration shell.⁸⁴

5 INORGANIC SOLIDS

Since the sodium nucleus has a large quadrupole moment and a low quantum spin number I , it has a significant second-order quadrupolar shift given by $-(1/30) \cdot (\nu_Q/\nu_0)^2 \cdot [I(I+1) - 9m(m-1) - 3] \cdot (1 + \eta^2/3)$, where $\nu_Q = 3\chi[2I(I-1)]^{-1}$, ν_0 is the Larmor frequency, and η is the asymmetry factor.⁸⁵⁻⁸⁸ The attendant correction is in the range 0–10 ppm. Interferometric correlation of the first- and second-order shifts enhances resolution,⁸⁹ due in part to population transfers between single-quantum (SQ) and double-quantum (DQ) states.⁹⁰ Both the SQ and the DQ ^{23}Na resonances in a single crystal of sodium nitrate share lineshapes with the same second moment.⁹¹ The length of the exciting pulse depends on the transition observed. With the central $m = +\frac{1}{2} \rightarrow -\frac{1}{2}$ coherence it is $\pi/4\gamma H_1$ (90°), whereas if one of the satellite $m = \pm\frac{3}{2} \rightarrow \pm\frac{1}{2}$ resonances is excited it is $\pi/\gamma H_1 2\sqrt{3}$. The amplitude of the FID following a 90° pulse thus depends on the precise resonance being excited. The FID amplitudes are in the ratio $1:\sqrt{4/10}:\sqrt{3/10}$ when the excitation is indiscriminate, applied to the sole center line, or to one of the satellites alone. Measurement of such pulse responses amounts to a measurement of the quadrupolar coupling constant χ .⁹² Of course, relatively high-resolution solid state spectra result from focusing exclusively on the central ($+\frac{1}{2}, -\frac{1}{2}$) resonance. It is broadened in a solid only by dipolar, chemical shift anisotropy and second-order quadrupolar broadening. Since the latter are $\propto B_0^{-1}$, the best results are achieved at the highest fields and spinning rates. Residual widths in the kHz range are typical with large 2–3 MHz quadrupolar coupling constants.^{93,94}

The state of Na^+ cations inside zeolites has been monitored.⁹⁵⁻⁹⁸ Other minerals such as β -gallate,⁹⁹ $\text{Na}^+\text{XZR}_2\text{Si}_x\text{P}_{3-x}\text{O}_{12}$,¹⁰⁰ lanthanide salts,¹⁰¹ β -alumina,¹⁰² the sodium phyllosilicate $\text{Na}_2\text{Si}_2\text{O}_5$,¹⁰³ and the polycrystalline salts of ADP and ATP^{104,105} have also been the topics of fine work.

6 ION TRANSPORT

Active transport is of the St. Christopher variety: an ionophore molecule grabs the sodium cation, divested of most or all its hydration shell, shields it from the lipophilic interior of a cell membrane, and disgorges it on the other side of the membrane where the Na^+ ion puts back on a coordination shell.

Passive transport is a canal crossing. Singly or in a queue, the sodium ions (accompanied by the chloride anions) pass through a channel set up through a cell membrane. Nature can build these channels (for instance from gramicidin A, a pentadecapeptide) so that the electrostatic field and charges on the inner walls of the channel help to bring along the migrating ions from one side of the membrane, or wall, to the other.

After a couple of pioneering studies of the gramicidin A channel by ^{23}Na NMR^{106,107} Dan Urry's group at the University of Alabama gave it their detailed and careful

attention from the beginning of the 1980s.^{108,109} As is often the case, the study of the natural structures prompted synthesis of artificial analogs such as that of a membrane-insertable, sodium cation conducting channel: kinetic analysis by dynamic ^{23}Na NMR was reported.¹¹⁰

Monensin-mediated¹¹¹ and nigericin-mediated¹¹² transport of sodium ions through phospholipid bilayers have been monitored by ^{23}Na NMR. Sodium-23 NMR measurement of the maximal rate of active sodium efflux from human red blood cells has been reported.¹¹³ Simultaneous observation with ^{23}Na and ^{31}P NMR gave insight into the coupling between in vivo sodium transport and phosphorus metabolism in sodium-loaded yeast^{114,115} and in *Streptococcus faecalis*.¹¹⁶ One- and two-dimensional magnetization transfer experiments applied to monensin-mediated transport gave a coherent overall description of transmembrane cation transport and of the kinetics of the sodium pump.^{117,118} The state of sodium in membranes of the sarcoplasmic reticulum was investigated.¹¹⁹

7 WHOLE CELLS

Saline aqueous solutions within organisms, as the internal medium of cells, are the remanent trace, the enduring memory, many think, of the composition of the primeval ocean: one more impetus for the determination of the concentration of these living solutions of ordinary table salt.

For determination of intracellular sodium concentration, discrimination between intra- and extracellular sodium ions is achieved by various means. One can use extracellular contrast reagents¹²⁰⁻¹²⁵ or apply a DQ filter, so that those sodium ions with biexponential relaxation outside the extreme narrowing condition can be selected.^{126,127} The contrast reagents used are lanthanide complexes either of the shift reagent¹²⁸⁻¹³¹ or of the relaxation agent type pioneered by Degani and Elgavish¹³² and reemphasized by Riddell and Southon as diamagnetic relaxation agents.¹³³ The intracellular concentrations thus determined agree nicely with those determined by flame photometry. Many such determinations were made, in mammalian proximal tubule,¹³⁴ in those of diabetics,¹³⁵⁻¹³⁷ in amphibian oocytes, ovulated eggs, and early embryos,¹³⁸ in renal brush border membrane vesicles,¹³⁹ in the halo-tolerant alga *Dunaliella salina*,¹⁴⁰ and in the halophilic bacterium *Halobacterium halobium*,¹⁴¹ in *Dictyostelium discoideum* amoeba,¹⁴² in kidney tubules,¹⁴³ also in vivo¹⁴⁴ in a wall-less strain of *Neurospora crassa*,¹⁴⁵ in reticulocyte,¹⁴⁶ and red blood cells^{147,148} submitted to drugs.¹⁴⁹ Sodium influxes in renal epithelial LLC-PK1/CL4 cells were monitored by ^{23}Na NMR.¹⁵⁰ In the late 1980s, removal of artifacts such as the invisibility of some of the sodium ions¹⁵¹⁻¹⁵⁴ or leakage through the DQ filter of extracellular ions led to combining the DQ filter and paramagnetic quenching of outer sodium,^{155,156} or to selective detection of intracellular sodium by coherence transfer.¹⁵⁷ The relaxation rates gave insight into the molecular environment of intracellular sodium.¹⁵⁸

8 TISSUES AND ORGANS

This is one of the earliest applications of sodium NMR. Tainted initially by misinterpretation (40% free sodium

coexisting with 60% bound sodium)^{159–171} it was set right by the appearance of the theoretical paper by Hubbard and by the Monoi reinterpretation^{172,173} in terms of the presence of membrane-bound sodium ions with two different transverse relaxations. The modern era of ²³Na studies of intact tissue was ushered in by the Chang and Woessner study¹⁷⁴ of skeletal muscle using T_1 and spin echo T_2 determination. The latter had both slow and fast components. Ordering by condensation around macromolecules was responsible, and more than 90% of the sodium ions were in such a 'bound' state, characterized by a small quadrupolar coupling constant < 0.17 MHz and slow tumbling with a $\tau_c > 10$ ms.¹⁷⁴ Another epochal paper recorded, shortly thereafter, by gated sodium NMR, the first images of a beating heart.¹⁷⁵ Numerous authors followed with studies of NMR measurements of intracellular and extracellular sodium in intact tissues,¹⁷⁶ such as muscle,^{177,178} heart,^{179,180} kidneys,¹⁸¹ the aorta of hypertensive rats,¹⁸² neoplastic and nonneoplastic human tissue,¹⁸³ and during ischemia and calcium-free perfusion.¹⁸⁴ Phosphorus-31 and ²³Na NMR were applied to the study of phosphate metabolites, intracellular pH, and intracellular sodium during liver hypoxia and recovery.^{185,186} Their joint use was also applied to sonicated cardiolipin sodium salt.¹⁸⁷ Membrane depolarization was detected by continuous sodium ion monitoring of rat hearts at 4 °C,¹⁸⁸ and during ischemia¹⁸⁹ ion transport was monitored¹⁹⁰ which obeyed a proton–sodium ions antiport mechanism.¹⁹¹

9 MAGNETIC RESONANCE IMAGING

Given its good NMR receptivity the ²³Na nucleus was a natural for imaging studies. Among the numerous applications, an early one was the study of tissue following a cerebral stroke.¹⁹² The same group also compared resected with normal organs.¹⁹³ Arthritic cartilage degradation can be followed.¹⁹⁴ Sodium imaging in conjunction with proton imaging of lung water¹⁹⁵ was performed and improved.¹⁹⁶ Use of surface coils and a DQ methodology monitors brain potassium and sodium.¹⁹⁷ Sodium chloride-rich kidney is an easy target for imaging.¹⁹⁸ A number of improved methodologies such as chemical shift imaging,¹⁹⁹ DQ filtered²⁰⁰ and triple quantum filtered²⁰¹ sodium imaging have been proposed in more recent years.

10 CONCLUSIONS

Of some interest to future historians is the choice of the periodical in which a particular study appears. In each discipline, authors are acutely aware of the pecking order. While one may safely assume that investigators will push their results into the most prestigious and therefore most widely 'read' journal, the editors see to it that the material published conforms to their vision of the subject matter encompassed by their journal. We state these self-evident behaviors, at the risk of belaboring the obvious, only because preparation of this manuscript revealed the existence of (i) a bandwagon—in the 1970s and in the 1980s, the *Journal of the American Chemical Society* was extremely receptive to physicochemical characterizations of inclusion complexes

between metallic ions and crown ethers or cryptands—and (ii) a preference—somewhat contradictory with the choice of the periodical of the greatest impact—for making a contribution appear as *methodological* rather than *applied*. Many a paper that could very well have appeared also in a biochemical/biophysical journal showed up instead in the *Journal of Magnetic Resonance*.

The ultraspecialization strikes this reviewer as paradigmatic science at its routine worst: to keep in the same rut, repeating similar work in order to associate one's name with a tiny portion of a vast field is a parody of free inquiry.

Thus we reach the end of this survey. Even though the picture painted is a composite, it is not unattractive. The prospects though may be somewhat grim. One can read recent history as gradual secession of the field from intrinsic scientific interest, as the money and the talent switch their allegiance to the biomedical side.

1 INTRODUCTION

The detection of NMR signals of low- γ nuclei with spin $I = \frac{1}{2}$ is a very difficult task in most cases, for the following reasons: owing to the low magnetic moment, the sensitivity of these nuclei is very poor, and owing to the missing electric and the small magnetic interaction of these nuclei, they are very slowly relaxing. If a sufficiently large indirect spin-spin coupling to another kind of nucleus with higher magnetogyric ratio exists, the signal of the low- γ nuclei may be enhanced by polarization transfer, or the spectrum of the low- γ nuclei may be detected indirectly by double resonance techniques; such methods are described in detail elsewhere (see *Double Resonance* and *Polarization Transfer Experiments via Scalar Coupling in Liquids*). With the greater and greater static magnetic fields B_0 available from superconducting magnets, the relaxation rates by chemical shift anisotropy increase proportionally to B_0^2 , and the relaxation times of anisotropically shielded nuclei are sometimes reduced to a value useful for pulsed Fourier spectroscopy. In general, however, the natural widths of NMR lines $\Delta\nu_{\frac{1}{2}} = (\pi T_2)^{-1}$ of spin- $\frac{1}{2}$ low- γ nuclei are far less than the instrumental linewidth, which is due to the inhomogeneity of the magnet used for the experiment, i.e., inhomogeneously broadened lines result.

The only way to avoid such inhomogeneously broadened NMR lines and the resulting loss of signal intensity in CW spectroscopy consists in broadening the NMR lines beyond the width of the instrumental line by adding paramagnetic substances to the sample. Unfortunately, other essential properties of the sample may be changed by such paramagnetic admixtures (e.g., shifts of the NMR lines or changes in their relative intensities). Moreover, the efficiency in reduction of the relaxation times of an unknown sample by paramagnetic ingredients cannot be predicted in most cases. Pulsed Fourier

spectroscopy, starting from thermal equilibrium, yields absorption lines with the same natural halfwidth, i.e., the resulting NMR lines are inhomogeneously broadened to the same instrumental linewidth. This loss of NMR signal may also be demonstrated in the time domain by the following example: the nucleus ^{109}Ag in a 1 M aqueous AgNO_3 solution in a field $B_0 = 2.1\text{ T}$ has a longitudinal relaxation time $T_1 > 1000\text{ s}$, whereas the decay time of the FID of such a sample contained in a cylinder of 20 mm diameter and 40 mm filling height in an optimally homogenized iron magnet is $T_2^* \approx 60\text{ ms}$. To observe the FID during $T_{\text{ac}} \approx 200\text{ ms}$, one must wait for the build-up time of thermal equilibrium (at least $3T_1$) $T_p \approx 1\text{ h}$; this shows clearly that the NMR signal may be received only during a small fraction $T_{\text{ac}}/T_p \approx 2 \times 10^{-4}$ of the total measuring time.

In pulsed Fourier spectroscopy, beginning with the pioneer work of Ernst and Anderson,¹ the results of a multitude of equal experiments are averaged, each of them starting from the thermal Boltzmann equilibrium, i.e. starting with the magnetization M_0 in the z direction (the direction of the static field B_0). In contrast to CW spectroscopy, pulsed Fourier spectroscopy offers a way to overcome the problem of these inhomogeneously broadened lines: the narrow NMR lines of very slowly relaxing nuclei may be broadened by saturation to any desired width in an exactly predictable way. To achieve this aim, the distance T_p between the periodically applied rf pulses must be reduced: $T_p \ll T_2^*$ or $T_p \gtrsim T_2^*$, with $T_2^* \ll T_2 \leq T_1$; then the magnetization vector M of the sample will perform a periodic motion with the period T_p , but M never reaches its thermal equilibrium value M_0 in the z direction. In this pulsed steady state of the nuclear spin system, a refocusing effect occurs for the magnetization vectors of all different spin isochromats, which shows some analogy to the well-known spin echo techniques of Hahn² and Carr and Purcell,³ with the modification by Gill and Meiboom,⁴ which was also introduced to FT spectroscopy by Allerhand and Cochran⁵ and called spin echo Fourier transform NMR. A spin echo technique including a steady state of the z magnetization was pointed out by Becker et al.⁶ and named driven equilibrium Fourier transform spectroscopy.

In contrast to all spin echo techniques, the steady state magnetization vector M is neither in the z direction nor perpendicular to the z axis during any time interval; i.e., M shows a periodic motion with the pulse period T_p in all three dimensions of the space. No exact adjustment of the flip angle Θ of the periodically applied rf pulses is required; a misadjustment of Θ results in a changed steady state but it is not cumulative. But, in contrast to the normal FT spectroscopy starting from thermal equilibrium, the steady-state magnetization M depends strongly on the free precession angle of the magnetization during the pulse period in the rotating frame: $\Phi = (\omega_0 - \omega_c)T_p$. Such a steady state of all three components of M was first observed by Bradford et al.,⁷ and was analyzed in detail and demonstrated with water protons by Carr.⁸ Unfortunately this steady-state technique could not be introduced into NMR spectroscopy at that time, since digital signal averagers and efficient computers to perform the Fourier transformation were not then available.

However, this situation changed when, in the second half of the 1960s signal averagers and on-line computers became available. Only a few months after the pioneer work of Ernst

and Anderson,¹ the extremely weak NMR signal of the spin- $\frac{1}{2}$ nucleus ^{187}Os , which has one of the smallest magnetic moments and which is of low natural abundance (1.64%), was detected for the first time with the aid of this steady-state free precession technique.^{9,10} In the following years, the gain in sensitivity with the steady-state technique made possible the first systematic investigations or even the first detection of the NMR signal of a string of $I = \frac{1}{2}$ low- γ nuclei: ^{57}Fe , ^{107}Ag and ^{109}Ag , ^{207}Pb , ^{111}Cd and ^{113}Cd , ^{115}Sn , ^{117}Sn , and ^{119}Sn , ^{183}W , ^{89}Y , ^{103}Rh , and others (cited by Schwenk¹¹).

Because of the dependence of the steady-state magnetization M on the free precession angle Φ , this simple steady-state technique cannot be used to record multiline NMR spectra; each line of such a spectrum is attenuated and distorted in a different way, as pointed out by Ernst and Anderson¹ and in more detail by Freeman and Hill.¹² To cancel these phase and intensity anomalies, the results of different experiments must be combined, in which the frequencies of the lines of the irradiated rf spectra are changed relative to the Larmor frequencies of the NMR spectrum. Two ways were proposed to reach this goal: in the scrambled steady-state technique,¹² many experiments are performed with changed pulse period T_p , i.e., the distance of the lines in the irradiated rf spectrum is changed, whereas in the Quadriga technique¹³ only four experiments are performed with the carrier ν_c of the irradiated rf spectrum lowered by a quarter of the pulse repetition rate $1/T_p$ after each experiment. Ernst has pointed out a variant of the latter technique, four phase Fourier spectroscopy,^{14,15} which reduces the four FT calculations, and with this the amount of data to be processed, to a single FT calculation. By an appropriate selection of the pulse period $T_p \ll T_2^*$ or $T_p \gtrsim T_2^*$, either maximum sensitivity or maximum resolution can be achieved, respectively.

Steady-state free precession techniques also offer a way to determine extremely long relaxation times T_1 and T_2 in the range from 1 s to some hours.¹⁶ In contrast to spin echo techniques, no waiting time, either for the installation of the thermal equilibrium or for partial relaxation, is required during which no signal acquisition is possible. With the aid of these techniques the relaxation mechanisms of ^{109}Ag in the Ag^+ ion¹⁷ and in a molecule¹⁸ and of ^{57}Fe and ^{103}Rh in organometallic compounds¹⁹ were detected for the first time. To separate the contributions of different relaxation mechanisms to the relaxation rate of spin- $\frac{1}{2}$ low- γ nuclei, determinations of the relaxation times T_1 in at least two quite different fields B_0 must be performed. In the high fields of superconducting magnets, conventional techniques may be applied, whereas the extremely long relaxation times in the low B_0 of iron magnets cannot be measured without the application of such steady-state techniques. Moreover, slowly relaxing nuclei are excellent tools to study exchange phenomena^{20,21} (see *Relaxation Effects of Chemical Exchange*).

Steady-state free precession techniques have proved to be powerful tools in NMR spectroscopy of slowly relaxing spin systems. The signal-to-noise ratio attainable in a given measuring time may be increased by orders of magnitude with the aid of such techniques. This is why steady-state techniques presently are not only applied to low- γ nuclei but also used in fast imaging techniques.^{22,23} To carry out steady-state experiments on a pulsed FT NMR spectrometer requires no extra hardware—but does of course require appropriate software.

2 THEORETICAL ANALYSIS OF THE STEADY-STATE FREE PRECESSION TECHNIQUE

For the following considerations, one single species of spins with magnetogyric ratio γ may be assumed, and also the validity of the Bloch equations, i.e., the spin system can be described by the Larmor frequency $\nu_0 = \gamma B_0/2\pi$, the longitudinal relaxation time T_1 , and the transverse relaxation time T_2 . To establish a steady state in this spin system, equal, periodic, and coherent rf pulses of an oscillating magnetic field are applied to the sample. The repetition period T_p must be chosen to be small in comparison with the relaxation times T_1 and T_2 :

$$T_p \ll T_2 \leq T_1 \quad (1)$$

In order to be able to observe the NMR signal during the most part of T_p , the duration of the rf pulses may be chosen as

$$\tau_p \ll T_p \quad (2)$$

The amplitude $2B_1$ and the carrier frequency ν_c of the oscillating rf magnetic field must fulfill the condition

$$\Delta B = \left| \frac{2\pi(\nu_0 - \nu_c)}{\gamma} \right| = \left| \frac{\omega_0 - \omega_c}{\gamma} \right| = \left| \frac{\Delta\omega}{\gamma} \right| \ll B_1 \quad (3)$$

Moreover, the rf pulses must be coherent; i.e., the rf signal necessary to produce the oscillating magnetic field must be derived with the aid of electronic switches from a generator constantly running with the frequency ν_c ; the rf signal cannot be derived from an oscillator, which starts with arbitrary phase for each rf pulse. By this, it is guaranteed that one of the rotating components of the rf field is stationary (assumed in the u direction) in the coordinate system (u, v, z) rotating around the z axis with the angular velocity ω_c ; during the pulse, its amplitude is B_1 .

The magnetization vector M of the sample responds to these periodic, equal, and coherent rf pulses in the following ways.

1. During the rf pulse, M precesses around the u axis with angular velocity $\omega_1 = \gamma B_1$, and the total precession angle is $\Theta = \omega_1 \tau_p = \gamma B_1 \tau_p$. Relaxation effects may be neglected during this short time interval τ_p .
2. During the time interval of free precession (duration $T_p - \tau_p \approx T_p$), M precesses around the z axis with angular velocity $\Delta\omega = 2\pi \Delta\nu = 2\pi(\nu_0 - \nu_c)$; the total precession angle $\Phi = \Delta\omega T_p$. Superimposed on this motion are the relaxation effects: the exponential increase of the z component of M to the thermal equilibrium value M_0 with the time constant T_1 , and the exponential decay of the transverse component of M with the time constant T_2 .

The magnetization vectors in the rotating frame (u, v, z) may be denoted as $M(-0)$ immediately before the application of an rf pulse, $M(+0)$ immediately after the end of this rf pulse, and $M(-T_p)$ at the end of the following free precession period. In the steady state, which is established after a time considerably longer than T_1 [see equations (13) and (14)], M will always perform the same motion during each pulse period. In particular, the magnetization vectors immediately before the irradiation and at the end of the free precession, i.e., immediately before the next pulse, must be the same:

$$M(-0) = M(-T_p) \quad (4)$$

This condition leads to a linear, inhomogeneous system of equations for the steady state magnetization $M(-0)$. The

solutions were first derived by Ernst and Anderson¹ for the general case [without the steady-state condition, equation (1)]. The special solutions for the steady state [equation (1)] and the additional condition

$$\Theta \gg T_p/T_2 \geq T_p/T_1 \quad (5)$$

are¹¹

$$\left. \begin{aligned} \frac{M_u(+0)}{M_0} &= \frac{M_u(-0)}{M_0} = \frac{\sin \Theta \sin \Phi}{\Delta} \\ \frac{M_v(+0)}{M_0} &= -\frac{M_v(-0)}{M_0} = \frac{\sin \Theta (1 - \cos \Phi)}{\Delta} \\ \frac{M_z(+0)}{M_0} &= \frac{M_z(-0)}{M_0} = \frac{(1 + \cos \Theta)(1 - \cos \Phi)}{\Delta} \end{aligned} \right\} \quad (6a)$$

where

$$\Delta = (1 + \cos \Theta)(1 - \cos \Phi) + 2(1 - \cos \Theta)T_1/T_2 \quad (6b)$$

The steady-state transverse component of $\mathbf{M}$, which is responsible for the induced NMR signal, becomes

$$M_R = M_0 \frac{|\sin \Theta| \sqrt{2 - 2 \cos \Phi}}{(1 + \cos \Theta)(1 - \cos \Phi) + 2(1 - \cos \Theta)T_1/T_2} \quad (7)$$

The free precession angle Φ appears as argument only of harmonic functions, which are periodic in multiples of 2π ; therefore, in all equations, Φ may be replaced by the excess free precession angle Φ_{ex} , which is defined by subtracting an integer multiple of 2π from Φ : $\Phi_{\text{ex}} = \Phi - 2\pi n$, so that Φ_{ex} falls in the range $0 \leq \Phi_{\text{ex}} < 2\pi$. Equation (7) shows clearly that M_R , and thus the NMR signal induced during the free precession period, depend only on the ratio T_1/T_2 but not on the absolute values of the relaxation times.

The strong dependence of M_R on the free precession angle Φ is shown in Figure 1 for the special case $T_1/T_2 = 1$. For $\Phi_{\text{ex}} = 0$, all components of the steady-state magnetization $\mathbf{M}$ vanish because of saturation of the spin system. This result may be seen in the frequency domain: the Fourier transform of the pulsed irradiation of the rf magnetic field is a discrete spectrum of lines with the frequencies

$$\nu_c \pm n/T_p, \quad n = 0, 1, 2, \dots \quad (8)$$

and the amplitudes

$$A(\nu_c \pm n/T_p) \propto \frac{\sin(n\pi\tau_p/T_p)}{n\pi\tau_p/T_p} \quad (9)$$

For $\Phi_{\text{ex}} = 0$, one of the sidebands of the irradiated spectrum coincides with the Larmor frequency ν_0 , the NMR transition is saturated, and all macroscopic magnetization vanishes. By considering either the frequency or time domains, it is concluded that the optimum case for a steady-state experiment is the choice of the free precession angle $\Phi_{\text{ex}} = \pi$ or the choice of the irradiation carrier frequency

$$\nu_c = \nu_0 \pm (n + \frac{1}{2})/T_p \quad (10)$$

This choice guarantees that the Larmor frequency ν_0 lies just in the middle between two irradiation lines, i.e., the maximum distance between ν_0 and any sideband of the irradiation spectrum.

Figure 1 Steady-state transverse magnetization (proportional to the NMR signal) during the free precession period as a function of the free precession angle Φ for various flip angles Θ . A sample with $T_1 = T_2$ is assumed

Under this optimum experimental condition, $\Phi_{\text{ex}} = \pi$ or equation (10), the maximum transverse component of the magnetization

$$M_{R,\text{opt}} = \frac{M_0}{2} \sqrt{\frac{T_2}{T_1}} \quad (11)$$

is reached, when pulses with the optimum flip angle

$$\Theta_{\text{opt}} = \arccos \frac{T_1/T_2 - 1}{T_1/T_2 + 1} \quad (12)$$

are applied.

The development of this steady state free precession [$\Phi_{\text{ex}} = \pi$ and irradiation of optimum flip angles Θ_{opt} , as given in equation (12)], starting from the unmagnetized sample ($\mathbf{M}(t = 0) = 0$), may be described by an exponential function:^{11,16}

$$M_R(t) = \frac{M_0}{2} \sqrt{\frac{T_2}{T_1}} (1 - e^{-t/T_{\text{opt}}^*}) \quad (13)$$

with the time constant

$$T_{\text{opt}}^* = \frac{1}{2}(T_1 + T_2) \quad (14)$$

Apart from rapidly damped oscillations, which are averaged out in a real experiment, each initial state $\mathbf{M}(t = 0)$ yields an exponential build-up of M_R as well as of M_z with the same time constant T_{opt}^* as given in equation (14).

3 RECORDING OF NMR SPECTRA WITH THE STEADY-STATE TECHNIQUE

In a real NMR experiment, a single species of a nucleus with one well-defined Larmor frequency is never investigated. The inhomogeneity of all magnets available today results in an inhomogeneously broadened NMR line, i.e., in a distribution of Larmor frequencies, usually characterized by its mean value $\langle \nu_0 \rangle$ and the decay constant $T_2' \approx T_2^*$. Slowly relaxing spin systems are characterized by the condition $T_2^* \ll T_2$.

Figure 1, each line will be affected by a special phase and intensity anomaly. To get rid of these distortions in the case of maximum sensitivity [the condition in equation (15)], either the distribution $D(\Phi_{\text{ex}})$ of the free precession angles of one line of the spectrum must be enlarged far beyond the separation $1/T_p$ of the lines of the irradiation spectrum, as given in equation (8), or the irradiation spectrum must be changed sometimes during the NMR experiment, in order to average the results of experiments with different free precession angles Φ_{ex} , i.e., to give each NMR line the same chance.

The first way—the enlargement of the distribution $D(\Phi_{\text{ex}})$ —may be accomplished by inserting a short homogeneity spoil pulse at an arbitrary time during the pulse period T_p . In doing this, the steady state is not destroyed at all, and all Larmor frequencies remain unchanged during the time of observation of the signal; examples and experimental hints are given by Schwenk.¹¹ Unfortunately, in samples of low viscosity, diffusion effects during the interval T_p between homogeneity spoil pulses may reduce the NMR signal.

The second way—the change of the irradiation spectrum—may be accomplished in two different manners. The first consists in a random variation of the pulse period T_p after a batch of pulses. In doing this, the rf spectrum [equation (8)] is stretched or compressed, with the carrier frequency ν_c as a fixed point. Outside a frequency range near ν_c , this scrambled steady-state technique¹² changes the free precession angle to be equally distributed in the range $0 \leq \Phi_{\text{ex}} \leq 2\pi$,

and averaging the results of all such experiments cancels phase and intensity anomalies. The second manner of changing the irradiation spectrum consists of a linear shift of the carrier: four experiments with the carrier frequencies

$$\nu_{c,\rho} = \nu_c - \rho/4T_p, \quad \rho = 0, 1, 2, 3 \quad (23)$$

must be performed; the complete irradiation spectrum is shifted to lower frequencies by $\rho/4T_p$. The accumulated NMR signals $S_\rho(t)$ or $S_\rho(n)$, as described by equations (16) and (17), must be Fourier transformed separately to give four resonance curves $I_\rho(x)$, as described by equation (19). Shifting back these curves $I_\rho(x)$ by defining four different abscissa scales $z = x - \frac{1}{4}\rho$, the absorption curves $I_\rho(z)$ may be added, $I(z) = \sum_{\rho=0}^3 I_\rho(z)$, to get the undistorted spectrum. This Quadriga-FT technique (QFT),¹³ with only four experiments, reduces phase and intensity anomalies to less than 1% of the desired signal. Many details, experimental hints, and examples are given by Schwenk.¹¹ The QFT signal attainable within a given measuring time is 60% of that attainable with a normal steady-state free precession experiment ($T_p \ll T_2^*$ and $\Phi_{\text{ex}} = \pi$); this is the price to pay for the constant sensitivity throughout the total frequency range. Hence, in the case of maximum sensitivity, the QFT signal-to-noise ratio becomes

$$\frac{(S/N)_{\text{QFT}}}{(S/N)_{\text{therm equil}}} \approx \frac{3}{5} \sqrt{\frac{T_2}{T_2^*}} \quad (24)$$

Figure 3 ^{57}Fe NMR spectrum of a three-nuclear iron complex recorded with the Quadriga-FT technique to achieve maximum sensitivity: $1/T_p = 83 \text{ Hz}$, $\Theta = 57^\circ$ (optimum for unknown ratio T_1/T_2). A measuring time of $4 \times 12 \text{ h} = 2 \text{ days}$ was spent for this spectrum of the unenriched sample

Figure 4 ^{31}P NMR spectrum of the hypophosphite ion recorded with the quadriga technique to achieve maximum resolution in a less homogeneous field B_0 : $1/T_p = 20 \text{ Hz}$, $\Theta = 44^\circ$ (optimum for the ^{31}P relaxation times $T_1 \approx 1 \text{ s}$ and $T_2 \approx 270 \text{ ms}$). The total measuring time was about 4 min

Of course, this QFT technique may be applied with the condition in equation (15) to get maximum sensitivity, as well as with the condition in equation (22) to get maximum resolution. Examples of both cases are given in Figures 3 and 4.

The same four irradiation spectra may be achieved by phase shifts of the carrier signal by 0 , $\frac{1}{2}\pi$, π , and $\frac{3}{2}\pi$ from pulse to pulse instead of lowering the carrier frequency ν_c . This four-phase Fourier spectroscopy, proposed by Ernst,¹⁵ enables the coaddition of the NMR signals in time, $S_\rho(t)$, from all four experiments, and therefore requires only one Fourier transformation.

4 MEASURING TECHNIQUES FOR EXTREMELY LONG RELAXATION TIMES

The steady state magnetization $M(t)$ is neither purely longitudinal nor purely transverse during any time interval. Therefore steady-state techniques are not suitable to study purely longitudinal or purely transverse relaxation. The results of two experiments must be combined to evaluate T_1 and T_2 .

In the T_1/T_2 experiment, the amplitudes of the established steady state of the sample are determined for some different flip angles in the range $0^\circ \leq \Theta \leq 90^\circ$. Equation (7), describing the transverse component M_R of the magnetization, contains, besides the flip angle Θ and the free precession angle Φ (which should be adjusted to $\Phi_{\text{ex}} \approx \pi$), the two unknown quantities M_0 and the ratio of the relaxation times T_1/T_2 . With the aid of a Gaussian least-squares fitting routine, this ratio of the relaxation times as well as the signal amplitude corresponding to the equilibrium magnetization M_0 may be evaluated. The necessary calibration of the flip angles Θ is described in detail by Kronenbitter and Schwenk¹⁶ and Schwenk,¹¹ and many experimental hints and examples are given there. Figure 5 shows the results of such T_1/T_2 experiments with some nuclei in different chemical environments.

In the $T_1 + T_2$ experiment, the development of the transverse magnetization $M_R(t)$ starting from the totally unmagnetized state of the sample $M(t=0) = 0$ (or starting from any other initial state of the sample) is observed. To investigate this development of the NMR signal as a function of the time elapsed since demagnetization, the following block averaging technique is used. The signal is observed during a time interval of about $3T_{\text{opt}}^*$; this interval is split into L parts (about a dozen) of the duration T_{ac} . During the ν th time interval $\nu T_{\text{ac}} \leq t \leq (\nu + 1)T_{\text{ac}}$ ($\nu = 0, \dots, L - 1$), the NMR signal is accumulated in block ν of the memory in the time-averaging computer. Of course, this acquisition time T_{ac} , governed by the relaxation times of the sample, is far too short to achieve a sufficient signal-to-noise ratio. Therefore this development must be repeated frequently and the signal added to the corresponding block in the computer memory; i.e., a dynamic steady state is performed in the spin system. The demagnetization of the sample within the shortest time is described in detail by Kreibich and Schwenk;²⁵ a higher range of this dynamic steady state may be achieved by an inversion of the magnetization rather than by a destruction. This development of the transverse magnetization M_R is described in equations (13) and (14), for the special case $\Phi_{\text{ex}} = \pi$ and $\Theta = \Theta_{\text{opt}}$ [as given in equation (12)]; for the arbitrary

Figure 5 Results of some T_1/T_2 experiments with the following nuclei and samples: ^2H in D_2O ; ^{57}Fe in butadiene- $\text{Fe}(\text{CO})_3$, 2.9 M in C_6D_6 ; ^{183}W in WF_6 , neat liquid; ^{109}Ag in a 12 M solution of AgNO_3 in acetonitrile at 298 K; ^{73}Ge in GeCl_4 , neat liquid; and ^{89}Y in a 3 M aqueous solution of $\text{Y}(\text{NO}_3)_3$ with pH 1.3

case, see Kronenbitter and Schwenk¹⁶ and Schwenk.¹¹ By a Gaussian least-squares fitting routine, the time constant T^* as well as the signal amplitude of the totally established steady state may be evaluated from the absorption maxima of $I_\nu(x = \kappa)$; equation (19), as determined by Fourier transformation of the signal in block ν of the memory. Figure 6 shows an example of such a $T_1 + T_2$ experiment.

A detailed description with additional examples, experimental hints and a discussion of the systematic errors caused by inhomogeneities in the fields B_0 and B_1 may be found in Kronenbitter and Schwenk¹⁶ and Schwenk.¹¹

5 INVESTIGATION OF NUCLEI WITH SPIN-SPIN COUPLING

Two types of scalar coupling of the $I = \frac{1}{2}$ low- γ nucleus X under investigation to another nucleus A must be distinguished.

5.1 Heteronuclear Coupling

Here, A is not the same isotope as X. In this case, nucleus A is not affected by the steady-state experiment performed with nucleus X. However, the steady state of X is affected by the longitudinal relaxation of A. A change in the eigenstate of nucleus A results in a change in the Larmor frequency of X by the coupling constant J . Owing to this, the steady state of X is disturbed, depending on the longitudinal relaxation time T_1^A of nucleus A; the worst case is $T_1^A \approx T_p$. In this worst case,

Figure 6 Results of a $T_1 + T_2$ experiment with a binuclear Rh complex, about 0.1 M in CH_2Cl_2 at 296 K. $\text{Rh}_1 \equiv \text{X}$ and $\text{Rh}_2 \equiv \text{A}$ are weakly spin–spin coupled. Rh_1 was investigated; i.e., $\Phi_{\text{ex}}(\text{Rh}_1) = \pi$ was chosen. By application of semiselective triplet rf pulses, Rh_2 was not affected by the irradiation in the first experiment, whereas by single pulses with $\Phi_{\text{ex}}(\text{Rh}_1) = \pi$ and $\Phi_{\text{ex}}(\text{Rh}_2) = 0$ in the second experiment, the Rh_2 NMR line was saturated, resulting in a shorter $T^*(\text{Rh}_1)$ because of cross relaxation

a coupling constant J with $|J|/T_p \approx 5\%$ is sufficient to destroy the steady state of X, as pointed out by Schwenk.¹¹ In most cases, a scalar coupling of X to an $I = \frac{1}{2}$ nucleus with high γ , e.g., to ^{19}F , ^{31}P , or a similar nucleus, destroys the steady state of nucleus X. Fortunately, such a coupling of X to an $I = \frac{1}{2}$ nucleus A with considerably stronger magnetic moment offers a way to improve the signal of spins X by spin transfer or to record the spectrum of spins X by a double resonance experiment.

5.2 Homonuclear Coupling

Here, A and X are nuclei of the same isotope in a molecule, they differ only in their chemical shifts δ_X and δ_A . In general, rf irradiation affects both nuclei X and A; i.e. a double resonance experiment is performed, which must be treated theoretically with the density matrix²⁶ or product operator formalism,²⁷ rather than with the Bloch equations. In contrast with an NMR experiment affecting only one kind of nuclei X or A, in such a double resonance experiment, not only the signal intensities of both nuclei X and A but also their relaxation times are changed. In the case of weak spin–spin

coupling $|J| \ll |\delta_X - \delta_A|$, such a double resonance experiment can nearly be avoided by irradiation of semiselective rf pulses with full intensity for nuclei X and vanishing spectral intensity for nuclei A. Such semiselective pulses may be doublets¹¹ or triplets,²⁸ which (in the time domain) act on nuclei X in just the same manner as a single rf pulse, but restore the magnetization of spins A, assumed to be in the z direction immediately before the semiselective pulse, to exactly the same direction after it. Semiselective doublets allow such a restoration of M in the z direction only for one spin isochromat with distinct Larmor frequency, whereas with semiselective triplets, the same result may be achieved in a range of Larmor frequencies sufficient for a real inhomogeneously broadened NMR line. A steady state of the nuclei X stimulated with semiselective triplets consists of three pulses and three intervals of free precession and relaxation; this, of course, requires amendment of the formulas [equations (7), (13), and (14)] necessary to evaluate the relaxation experiments. Figure 6 shows two results of the $T_1 + T_2$ experiment performed with the ^{103}Rh nucleus shifted to lower frequency in *cis*-[(CpRh)₂COT] (the two ^{103}Rh Larmor frequencies differ by 960 Hz at 2.114 T and the coupling constant is $|J(\text{Rh}, \text{Rh})| < 5$ Hz). Selective irradiation yields a considerably longer T^* than wideband irradiation, since cross relaxation is avoided (see *Relaxation Processes in Coupled-Spin Systems* and *Relaxation Processes: Cross Correlation and Interference Terms*).

1 NMR SPECTROSCOPIC PROPERTIES OF ^{33}S , ^{77}Se , AND ^{125}Te AND EXPERIMENTAL TECHNIQUES

The three chalcogens sulfur, selenium, and tellurium are rare elements in NMR spectroscopy. Although sulfur is important in inorganic, organic and biochemistry, only few scattered NMR spectroscopic studies exist, a fact which is due to the rather unfavorable nuclear properties of its only NMR-active isotope ^{33}S . So, this nucleus is of interest only for specialists and will probably not see general application. On the other hand, the heavier chalcogen isotopes ^{77}Se and ^{125}Te are comparable to ^{13}C in their properties or even superior, but these elements are much less abundant in chemistry. However, during the 1980s this situation changed, at least for ^{77}Se , when organoselenium chemistry was developed into a valuable synthetic tool, especially for regio- and/or stereoselective reactions and other stereochemical applications.

This article is not intended to be a comprehensive review. NMR spectroscopy of all three nuclei has been reviewed several times.^{1–9,32} In order to avoid an extensive literature list, data and facts are quoted only if they have not yet appeared in any earlier review.

1.1 Sulfur-33

As can be seen from Table 1, ^{33}S is the only quadrupolar nucleus, and so large linewidths have to be expected. Indeed, this is the main reason why applications of ^{33}S NMR spectroscopy are so rare.^{1,2} The quadrupolar moment of ^{33}S makes its relaxation so effective that T_1 and T_2 values are very often in the range 10–100 ms, making ^{33}S lines several kilohertz wide.^{1,2} A possible way to attenuate such signal line-broadening effects is to apply higher temperatures and to use low-viscosity solvents, because linewidths are dependent on the isotropic tumbling correlation time of the molecule (τ_c). The relatively low resonance frequency of ^{33}S leads to acoustic-ringing effects in the probehead which can cause severe baseline distortions so that the signal may even be invisible. Several methods have been proposed to overcome this problem, for example the application of high external

fields and special pulse sequences (e.g. RIDE).^{1,2,10} The unfavorable R_c value (Table 1) is due to the low resonance frequency and the low natural abundance, but this difficulty can be overcome. The small relaxation times allow a high repetition rate for FID sampling. In many cases, it may be possible to accumulate 10 to 100 transients per second. Nevertheless, ^{33}S signals with halfheight widths lower than 1 kHz occur only if there is high symmetry at the sulfur atom, as for example when it is surrounded tetrahedrally by four atoms as in sulfates or sulfones. There are only few exceptions, among them the cylindrical molecules CS_2 and COS . Unfortunately, symmetry is a very severe restriction to the application of ^{33}S NMR because many sulfur compounds of interest such as thiols, sulfides, disulfides and sulfoxides do not meet this condition.

Temperature and medium effects on ^{33}S chemical shifts are low compared with the experimental uncertainty associated with line broadening. ^{33}S linewidths governed by relaxation times vary with changes in concentration, solvent, and temperature. These dependences can be exploited for measuring activation energies of molecular reorientation. So, it is possible to monitor differences in the molecular association of sulfur-containing solutes and solvent molecules.¹

1.2 Selenium-77 and Tellurium-125

The situation is much better for selenium and tellurium because all their NMR-active isotopes are spin- $\frac{1}{2}$ nuclei where extreme line broadening generally does not occur. Consequently, there are many more publications in this field, and they have been reviewed several times.^{3–9} The receptivity (R_c in Table 1) of ^{77}Se is about three times larger than that of ^{13}C . If one considers that, normally, NOE signal enhancements are not observed (see below), ^{77}Se can be regarded as equivalent to ^{13}C in its sensitivity. The element tellurium offers two isotopes. However, inspection of their R_c values (Table 1) clearly shows why ^{125}Te has been used in the overwhelming majority of tellurium NMR studies. Only in compounds with more than one tellurium atom might it be rewarding to measure ^{123}Te signals in order to identify ^{123}Te – ^{125}Te coupling constants. No significant differences in the chemical shifts of the two isotopes have been observed, as expected.

The longitudinal relaxation of ^{77}Se and ^{125}Te is governed by spin rotation (SR) and, particularly at higher fields, chemical shift anisotropy (CSA) mechanisms.⁷ In general, dipolar relaxation does not play a significant role, and so NOE signal enhancements do not occur (except for selenols, R–SeH , where a proton is directly attached to ^{77}Se). Typically, T_1 values are in the range of 1–30 s and, consequently, repetition rates should be in the same range. In the solid state the relaxation time of ^{77}Se can become very long so that high-resolution magic angle spinning (MAS) experiments without cross polarization (CP) will generally produce signals only with very long relaxation delays.

^{77}Se and ^{125}Te may display rather strong temperature dependences of their chemical shifts, a property which they share with many other heavy nuclei. The signals may be shifted by several parts per million over a range of only a few degrees Celsius so that extreme care is necessary if high-resolution ^{77}Se or ^{125}Te NMR is required.¹¹ This is particularly

^aDifferent values are from different literature sources.

the case with diorganylselenides and -tellurides; interestingly, the temperature dependence of diorganyltellurium dihalides is much less.^{11b} Concentration dependence is not severe and can even be neglected if low or moderate concentrations are used. Changing solvents, however, may shift a ^{77}Se signal considerably. For example, a shift of about 22 ppm to low frequency is observed for a 5% solution of Me_2Se when going from C_6D_{12} to $(\text{CD}_3)_2\text{SO}$.¹² Analogous effects are expected to be even more pronounced for ^{125}Te .⁷

1.3 Referencing

Correct referencing is important when documenting and comparing NMR data. The most commonly used standards are: $(\text{NH}_4)_2\text{SO}_4$ or Cs_2SO_4 in water for ^{33}S ; Me_2Se in CDCl_3 for ^{77}Se ; and Me_2Te in CDCl_3 for ^{125}Te ; all with the chemical shift $\delta = 0$ and used as external reference. CS_2 with a ^{33}S chemical shift of $\delta = -333$ ppm has been recommended as an alternative for the sulfate ions. Since Me_2Se and Me_2Te are liquids with a very unpleasant smell, many workers prefer to use low concentration CDCl_3 solutions of commercially

available and easy to handle solids such as Ph_2Se_2 [$\delta(^{77}\text{Se}) = 463$ ppm] and Ph_2Te_2 [$\delta(^{125}\text{Te}) = 422$ ppm], respectively, as internal or external standards. It should be noted that an absolute ^{33}S shielding scale has been proposed according to which $(\text{NH}_4)_2\text{SO}_4$ and CS_2 resonate at $\delta = +249$ and $+581$ ppm, respectively.^{1,2}

2 ^{33}S NMR AND ITS APPLICATIONS

2.1 ^{33}S Chemical Shifts

^{33}S chemical shifts span a range of about 1000 ppm. The δ values of some representative compounds along with their signal linewidths (where available) are listed in Table 2 together with some typical resonance ranges of certain inorganic and organic sulfur functionalities. However, it should be noted that many values are imprecise due to extensive line broadening (see Section 1).

Four regions can be identified.^{1,10} In order of increasing frequency these are: (a) singly bonded sulfur, (b) multiply

bonded sulfur, (c) sulfur in a delocalized π system, and (d) S=O bonds. Although, in principle, this is correct, the four ranges do overlap severely and exceptions occasionally occur so that ^{33}S chemical shifts are by no means good parameters for indicating the bonding situation of sulfur.

Sulfuric acid and sulfates generally resonate around $\delta = 0$ ppm. The thiosulfate anion ($\text{S}_2\text{O}_3^{2-}$) has two sulfur atoms in different positions but only one ^{33}S signal could be measured ($\delta = 34$ ppm). ^{33}S depletion of the thiosulfur and estimation of the electric field gradients enabled the signal observed to be assigned to the internal sulfur atom.¹

Strong diagnostic ^{33}S deshieldings have been observed when oxygen is replaced gradually by sulfur in the thiomolybdate anions (1)–(4) (Table 3).¹⁰ Thiotungstates show the same trend, but the ^{33}S atoms are shielded by 179–199 ppm when compared with the analogous thiomolybdate ions.¹⁰ Recently, ^{33}S chemical shifts of Cu(I) and Ag(I) complexes with MoS_4^{2-} and WS_4^{2-} have been reported.¹³ ^{33}S signals of metal sulfides and sulfates in the solid state were recorded.¹ Whereas a large number of sulfates resonate uniformly between $\delta = -13$ and 0 ppm, the resonances of sulfides vary over a wide range (more than 600 ppm), e.g. Li_2S ($\delta = -680$ ppm), SrS ($\delta = -290$ ppm), and BaS ($\delta = -42$ ppm). The explanation is the existence of different bond characters and ionicities in the crystal.¹

Whereas the sulfur nucleus in thiols and thioethers is strongly shielded ($\delta = -300$ to -510 ppm), oxidation to sulfoxides leads to 300–400 ppm deshielding. Further oxidation to sulfones, however, does not significantly change the $\delta(^{33}\text{S})$ values. This pattern is also seen in ^{77}Se chemical shifts (see Section 3.1). Two positively charged sulfonium salts have been measured, and their signals appear at the high-frequency end of the δ scale (*S*-methylthiolanium, $+420 \pm 50$ ppm; *S*-methylthianium, $+340 \pm 50$ ppm).^{1,2} Interestingly, three- and four-membered ring compounds are exceptions [see, for example, (5)–(7)] in that the sulfur is much more shielded than in the corresponding acyclic and cyclic analogs of larger ring sizes.^{1,2} The same has been observed for other nuclei (^1H , ^{13}C , and ^{17}O) in or at three-membered rings.

Substituent effects of alkyl and aryl groups on the ^{33}S chemical shift of diorganyl sulfones have been determined. In many cases good additivities of alkyl, alkenyl, and aryl group effects have been found (for details see Hinton¹), and correlations of $\delta(^{33}\text{S})$ values with those of ^{13}C and ^{17}O in analogous compounds as well as with Taft σ^* parameters could be established.¹⁴ Substituents in 3- and *trans*-3,4-substituted thiolane 1,1-dioxides and 4-substituted 2-thiolene 1,1-dioxides influence the ^{33}S chemical shift according to their σ_1 parameter, although the δ values vary by only 10–12 ppm for a wide range of substituents (CH_3 to SO_3Cl).¹⁵ There is a similarity between the ^{33}S chemical shifts in sodium sulfonates ($\text{R}-^{33}\text{SO}_3^-$) and the ^{13}C shifts in carboxylates ($\text{R}-^{13}\text{COO}^-$),^{1,2} and good correlation has been found between ^{33}S chemical shifts in *para* substituted benzenesulfonates and the Hammett σ constants of the substituents.¹ Other authors correlate ^{33}S chemical shifts in the same class of compounds with inductive substituent effects (ρ_1)¹⁶ and $\text{p}K_a$ values.²

Table 3 Chemical Shifts and Linewidths of the Thiomolybdate Ions (1)–(4)

	$[\text{MoSO}_3]^{2-}$ (1)	$[\text{MoS}_2\text{O}_2]^{2-}$ (2)	$[\text{MoS}_3\text{O}]^{2-}$ (3)	$[\text{MoS}_4]^{2-}$ (4)
$\delta(^{33}\text{S})$	−25	+123	+240	+345
Linewidth (Hz)	200	250	170	38

Sulfonated naphthalene derivatives have been studied in terms of substituent effects on their ^{33}S chemical shifts.¹⁷ An $n_X \rightarrow \sigma_{\text{S-X}}^*$ interaction in sulfonyl halides ($-\text{SO}_2\text{X}$) has been proposed.¹⁸

Sulfoximines $[\text{R}-(\text{O}=\text{S}(\text{NR}'')-\text{R}')]^{-}$ resonate at lower frequencies than the corresponding sulfones $[\text{R}-\text{S}(=\text{O})_2-\text{R}']^{-}$, which may be due to the lower electronegativity of the doubly bonded NR group in the sulfoximine replacing the oxygen in the sulfone. However, the opposite is seen when sulfinimines $[\text{R}-\text{S}(=\text{NR}'')-\text{R}']^{-}$ are compared with the corresponding sulfoxides $[\text{R}-\text{S}(=\text{O})-\text{R}']^{-}$.^{1,2} On the other hand, ^{33}S chemical shifts in sulfonamides are quite similar to those in the sulfones.^{1,2}

The absorption range of the sulphones of about 60 ppm has led to the suggestion of using ^{33}S NMR spectroscopy in the analysis of sulfur-containing oils after oxidation of all sulfur species.^{1,2,19,20} In two instances, stereochemical effects on ^{33}S chemical shifts have been studied. It was shown that the diastereomeric sulfones (8) and (9) differ by 10 ppm.^{1,2} The diverging stereochemical position of the phenylsulfonyl group in the conformationally fixed cyclohexanes (10) and (11) is reflected by a 3 ppm difference in the ^{33}S chemical shifts.² Interestingly, the sulfur atom in the axial stereoisomer (11) is deshielded compared with that in (10), which is opposite to the general finding that γ -*gauche* substituent effects are shielding, a rule with only very few exceptions.²¹

2.2 ^{33}S Couplings

There are only few reported data on ^{33}S couplings. This is due to the short relaxation times associated with severely broadened signals (see below). Two-bond $^{33}\text{S}-^1\text{H}$ coupling constants of 3 and 4.5 Hz were measured for $\text{CH}_3-\text{SO}_2-\text{CH}_3$ and sulfolane,^{1,2} and a $^{33}\text{S}-^1\text{H}$ coupling constant of 6 Hz extracted from the signal of 2,5-dihydrothiophene 1,1-dioxide was attributed to a vicinal (three-bond) coupling to the alkenic protons.^{1,2,10} The exceptionally narrow linewidth of SF_6 (<1 Hz, corresponding to a relaxation time of $T_1 = 10 \pm 2$ s) allowed a precise determination of the one-bond $^{33}\text{S}-^{19}\text{F}$ coupling constant: $^1J(^{33}\text{S}, ^{19}\text{F}) = 251.8 \pm 0.2$ Hz.^{1,2}

3 ^{77}Se NMR AND ITS APPLICATIONS3.1 ^{77}Se Chemical Shifts

The total range of ^{77}Se chemical shifts is about 3300 ppm; the extremes are marked by selenoaldehydes and some molybdenum selenides (up to $\delta = 2400$ ppm) on the high-frequency side and bridging (μ) selenium in tungsten complexes ($\delta = -900$ ppm) on the low-frequency side. Figure 1 gives the resonance ranges of various selenium functionalities, and the ^{77}Se chemical shifts of selected compounds are collected in Table 4.

A number of reports have been published on elementary selenium. It is interesting to note that amorphous selenium (in a solid state ^{77}Se NMR experiment) resonates at $\delta = 865$ ppm, whereas hexagonal selenium is shielded ($\delta = 809$ ppm).²² Several cyclic selenium species have been identified in solution: neutral Se_6 , Se_7 , and Se_8 in CS_2 have been described, and their ^{77}Se chemical shifts were found to be in a similar range to those of solid selenium ($\delta = 685$, 998, and 615 ppm, respectively).²³ Other six- to eight-membered rings with selenium atoms replaced by sulfur and tellurium to various extents also absorb in these ranges, and again the chemical shifts of the seven-membered rings are higher than those of the others (about $\delta = 980$ to 1100 ppm).^{23,24} Se_4 dications as well as the mono-, di-, and tritellura derivatives thereof, generated in sulfuric acid or other Lewis acid solutions, were investigated. They form four-membered rings and, expectedly, their signals were found at very high frequencies ($\delta = 1432$ to 1948 ppm).^{9,25}

The ^{77}Se chemical shifts in selenium halides (SeX_2) reveal strong deshieldings with decreasing electronegativity of X in the series X = Cl ($\delta = 1758$ ppm), Br ($\delta = 1474$ ppm)^{4,5,7} and I ($\delta = 814$ ppm).²² The same deshielding, but with an opposite trend in the halogen effects, is found for the oxygenated species: SeOF_2 ($\delta = 1378$ ppm), SeOCl_2 ($\delta = 1479$ ppm), and SeOBr_2 ($\delta = 1559$ ppm).^{4,6} On the other hand, electropositive substituents such as H_3E (E = Si and Ge) attached to selenium lead to very strong shieldings ($\text{H}_3\text{E}-\text{Se}-\text{EH}_3$: $\delta = -666$ and -612 ppm, respectively),^{4,6} which are only exceeded by selenide ions in alkaline aqueous solution such as K_2Se ($\delta = -670$ ppm).²⁶ The highest shielding for a nonmetallic compound reported in the literature is the one due to a combination of the two influences in silicon-substituted selenides: $\text{H}_3\text{Si}-\text{Se}^-\text{Li}^+$ ($\delta = -736$ ppm).⁵ A general trend to deshielding with increasing electronegativity of substituents

directly attached to selenium in $\text{R}-\text{Se}-\text{X}$ (R = organyl) is observed [see (12)–(16)]⁷ although additional substituents or atomic groups play an important role and may even overrule the trend; e.g. see the C–Se–N compounds (17)–(20) where the ^{77}Se chemical shift difference between $\text{Ph}-\text{Se}-\text{NH}-\text{Bu}^t$ and $(\text{CF}_3-\text{Se})_3\text{N}$ is 1000 ppm!^{7,27}

$\text{Ph}-\text{Se}-\text{Cl}$ (12) ($\delta = 1039$ ppm)	$\text{Ph}-\text{Se}-\text{NMe}_2$ (13) ($\delta = 924$ ppm)	$\text{Ph}-\text{Se}-\text{Br}$ (14) ($\delta = 867$ ppm)	$\text{Ph}-\text{Se}-\text{SMe}$ (15) ($\delta = 514$ ppm)
$\text{Ph}-\text{Se}-\text{SeMe}$ (16) ($\delta = 447$ ppm)			
$\text{Ph}-\text{Se}-\text{NH}-t\text{-Bu}$ (17) ($\delta = 617$ ppm)	$\text{Ph}-\text{Se}-\text{morpholino}$ (18) ($\delta = 926$ ppm)	$\text{F}_3\text{C}-\text{Se}-\text{NCO}$ (19) ($\delta = 1104$ ppm)	$(\text{CF}_3-\text{Se})_3\text{N}$ (20) ($\delta = 1617$ ppm)

The structure of alkyl substituents in dialkyl- and arylalkyl selenides has a great influence on the ^{77}Se shielding, a behaviour that is analogous to, although stronger than, what has been found for other nuclei such as ^{13}C and ^{17}O . α Effects are large, as shown by comparing $\text{PhSe}-\text{H}$ ($\delta = 145$ ppm) and $\text{PhSe}-\text{Me}$ ($\delta = 197$ ppm),⁷ but β effects are even larger: replacement of a hydrogen atom at an α -methyl group leads to a 100–120 ppm deshielding. So, for example, the difference between Me_2Se ($\delta = 0$ ppm) and $\text{Me}-\text{Se}-\text{Bu}^t$ ($\delta = 294$ ppm) corresponds to three methyl groups ($\text{Me} \rightarrow \text{Bu}^t$) and that between Me_2Se and Pr_2^iSe ($\delta = 466$ ppm) to four methyl groups ($2 \text{ Me} \rightarrow 2 \text{ Pr}^i$).^{6,7} Analogous trends have been detected for phenylselenenylalkanes ($\text{PhSe}-\text{R}$),²⁸ alkylselenols (RSeH), and alkylselenolates (RSe^-Na^+), but in dialkyl diselenides (RSeSeR) the deshielding is attenuated to about 65 ppm.^{6,7} Fluorine atoms in the β -position lead to deshieldings similar to those of methyl groups: $(\text{CF}_3)_2\text{Se}$, $\delta = 698$ to 725 ppm (the data in the original papers differ a little).⁷ However, replacing fluorine by the less electronegative chlorine affords a further strong deshielding: $\text{CF}_3\text{Se}-\text{CCl}_3$, $\delta = 953$ ppm.⁷ This apparently paradoxical observation has been explained as being due to the differences in the hyperconjugation or polarizability of these two halogens.⁷ γ Effects are substantially shielding: e.g. $\text{PhSe}-\text{Et}$ ($\delta = 325$ ppm) and $\text{PhSe}-\text{Pr}^n$ ($\delta = 288$ ppm); $\Delta\delta = -37$.^{6,7,28} An inspection of rigid cyclohexane derivatives with selenium fixed in an axial position (two γ *gauche* methylene groups) shows that the magnitudes of these γ effects are very similar (35–40 ppm).^{11a} Thus it was concluded that molecular fragments such as $\text{PhSe}-\text{C}-\text{C}-\text{C}$ prefer *gauche* conformations.²⁸ Substituent effects beyond the γ position are more or less negligible. The large magnitudes of α to γ effects have been discussed in terms of intramolecular polarizability effects, which act in parallel to intermolecular effects, thus causing a large solvent dependence of the ^{77}Se chemical shifts.⁷

The investigation of a number of selenoanisoles ($\text{Ph}-\text{Se}-\text{Me}$) substituted at the aromatic ring revealed that the ^{77}Se chemical shift can be expressed by a linear combination of parameters σ_I and σ_R , the inductive and resonance parameters, respectively, in the dual substituent parameter (DSP) approach.²⁹ There is a different linear relationship for each position, *ortho*, *meta*, and *para* (for details see Baiwir⁶ and Luthra and Odom).⁷ Selenoesters $[\text{R}-\text{C}(=\text{O})-\text{Se}-\text{R}']$ have also been studied intensively.⁷

Se_8 (in CS_2)	615				

**Figure 2** ^{77}Se chemical shift ranges of compounds containing $\text{C}=\text{Se}$ groups (excluding metal complexes)

Oxidation of Se(II) to Se(IV) generally leads to considerable deshielding as can be shown in many cases: Me_2Se ($\delta = 0$ ppm), Me_2SeBr_2 ($\delta = 389$ ppm), and Me_2SeCl_2 ($\delta = 448$ ppm).⁷ In a series of phenylselenylalkane selenium oxides high-frequency shifts of 450–630 ppm due to oxidation have been found.²⁸ The magnitudes of substituent effects caused by the alkyl groups are approximately four times smaller in the selenoxides than in the corresponding selenides.²⁸

Halogenated species, however, may show the opposite tendency: SeCl_2 ($\delta = 1758$ ppm) and SeOCl_2 ($\delta = 1479$ ppm) (see above) or CF_3SeCl ($\delta = 1077$ ppm) and CF_3SeCl_3 ($\delta = 953$ ppm).⁷

In general, Se(VI) species have clearly smaller δ values than the structurally related Se(IV) analogs; for example, H_2SeO_4 resonates at $\delta = 1001$ ppm and H_2SeO_3 at $\delta = 1300$ ppm.^{4,5,7} Similarly, $\text{CF}_3\text{SeO}_2\text{H}$ resonates at $\delta = 1231$ ppm, whereas the ^{77}Se chemical shift of $\text{CF}_3\text{SeO}_3\text{H}$ is only 981 ppm.³⁰

Compounds containing a $\text{C}=\text{Se}$ group show chemical shifts spread over nearly the whole known range of ^{77}Se chemical shifts. The largest value has been reported for the selenoaldehyde (21) ($\delta = 2398$ ppm, Figure 2)³¹ and the lowest for $\text{O}=\text{C}=\text{Se}$ ($\delta = -447$ ppm).⁷ Figure 2 shows the various ranges, which depend strongly on the atoms and substituents attached to the carbon of the $\text{C}=\text{Se}$ group. Correlations with

$n \rightarrow \pi^*$ transitions and with ^{17}O chemical shifts in $\text{C}=\text{O}$ analogs have been found.⁷

Hundreds of cyclic compounds with selenium in the ring(s) have been reported, but only a small selection can be presented here. A more comprehensive compilation is available.³² Annulation of conjugated ring systems to selenophene (22) can cause considerable shieldings 23–26.^{5–7} On the other hand, replacement of carbon by an electronegative element such as nitrogen shifts the ^{77}Se signal to high frequencies by up to 900 ppm [(27)–(29)].^{5–7} Interestingly, the size of the aliphatic ring annulated to the selenadiazole (29) has a considerable influence on the ^{77}Se chemical shift; apparently, the selenium nucleus reacts very sensitively to minor strain effects within the heterocycle caused by the different cycloalkene rings in (30)–(32).³³ Substituent effects have a great impact as well. In monosubstituted selenophenes they range from $\delta = 721$ ppm for 2-iodoselenophene down to $\delta = 513$ ppm for 2-fluoroselenophene.⁷ As expected, positively charged unsaturated ring systems strongly deshield selenium nuclei;²⁵ e.g. in (33), the chemical shift of which is the highest value reported so far.³⁴ Other interesting cyclic and caged structures such as (34)³⁵ and (35)³⁶ have been reported; here the chemical shifts follow the general trends of inductive and mesomeric influences encountered in open-chain selenium compounds. A transannular effect between the two silicon atoms in (37) deshields the bridging selenium atoms by more than 500 ppm as compared with (36) where no such through space interaction is expected.³⁷

Some hypervalent tetraarylselenium compounds, e.g. (38) and (39), have been measured at -100°C .³⁸ Surprisingly, their ^{77}Se chemical shifts do not deviate much from those of other divalent diaryl selenides ($\text{Ph}-\text{Se}-\text{Ph}$: $\delta = 402$ ppm).⁵⁻⁷

The δ values of selenium in $\text{P}=\text{Se}$ bonds are negative ((40)–(53)). This indicates a substantial contribution of the dipolar mesomeric form (II): $-\text{P}=\text{Se}$ (I) $\leftrightarrow$ $-\text{P}^+-\text{Se}^-$ (II). Only very few exceptions exist, e.g. $\text{Ph}-\text{P}(=\text{Se})\text{Cl}_2$ ($\delta = 149$ ppm)³⁹ and $(\text{NC})_2\text{P}(=\text{Se})-\text{Se}^- \text{K}^+$ ($\delta = 172$ ppm).⁴⁰ The chemical shifts depend strongly on the nature of the substituent at phosphorus (carbon or hetero atom), and the branching of carbon substituents also plays a significant role; for example, there is a nearly 100 ppm difference for the isomeric tripropylphosphine selenides (42) and (43).⁴¹ Very little is known about the stereochemical dependence of ^{77}Se chemical shifts in $\text{P}=\text{Se}$ groups, in contrast to the one-bond $^{31}\text{P}-^{77}\text{Se}$ coupling constant (see Section 3.2) which has been studied extensively, but mainly by recording ^{31}P NMR. The diastereomeric pair (52) and (53), however, clearly shows that selenium experiences a strong shielding in the axial position [(53), γ gauche effect].⁴²

^{77}Se NMR data for many selenium–metal compounds have been published and their appearance is rapidly increasing.³² These compounds can be classified into three different types: (a) selenium with covalent bonds to main group metals, (b) selenium σ -, π -, μ -, or η -coordinated to transition metal atoms, and (c) selenium being a member atom of ligands, but with other atoms (mostly phosphorus or nitrogen) coordinated to the metal atom.

3.1.1 Type (a) Compounds

Deshieldings, as compared to the corresponding selenide anions, are often observed when selenium is bonded to group 13, 14, or 15 elements: $\text{Sn}(\text{SeMe})_4$, $\delta = -127$ (MeSe^- , $\delta = -330$); $[\text{Pb}(\text{SePh})_3]^- \text{Na}^+$, $\delta = 127$ (PhSe^- , $\delta = 104$); or $\text{M}(\text{SePh})_3$ with $\text{M} = \text{As}$ ($\delta = 266$), $\text{M} = \text{Sb}$ ($\delta = 397$), or $\text{M} = \text{Bi}$ ($\delta = 311$ ppm).⁴³ But the reverse has also been reported ($\text{In}(\text{SePh})_3$, $\delta = 39$ ppm),⁴⁴ and high shieldings are found if selenium carries two metal atoms: $\text{Ph}_3\text{Pb}-\text{Se}-\text{PbPh}_3$ ($\delta = -454$ ppm).⁴⁵

3.1.2 Type (b) Compounds

^{77}Se chemical shifts of these complexes cover the whole shift range. In most cases the selenium atom is deshielded ($\delta = 200$ to 1500 ppm) as compared with the free selenium-containing ligand. The δ value of the terminal selenium atom (c) in the molybdenum complex (54) is one of the largest ever recorded; in the corresponding tungsten analog it is only $\delta = 1787$ ppm.⁴⁶ On the other hand, the spectra of the adamantane-like caged selenides (55) and (56) display rather low δ values.⁴⁷ Extremely strong shieldings have been observed in the case of the η^4 -cobalt complex (57) ($\delta = -727$ ppm) as compared with the free heterocycle with $\delta = -95$ ppm,⁴⁸ and a complex with selenium atoms linking two tungsten atoms, $[\eta^5\text{-Cp-W}(\text{CO}_3)_2(\mu\text{-Se})]$, $\delta = -900$ ppm, seems to have the smallest ^{77}Se chemical shift reported so far.⁴⁹ The π -complex (58) has a surprisingly low δ value;⁵⁰ one expects ^{77}Se chemical shifts of selenoaldehydes to be above 2000. Stereochemical assignments seem to be possible in platinum complexes. For example, the difference in ^{77}Se chemical shifts of the isomeric structures (59) (*cis*) and (60) (*trans*) is 83 ppm.⁵¹

(55) [X = Cd, δ = 28 ppm (terminal), -64 ppm (bridging)](56) [X = Zn, δ = 46 ppm (terminal), -7 ppm (bridging)](57) (δ = 727 ppm)
(Cp = η^5 -cyclopentadienyl)(58) (δ = 211 ppm)(59) (δ = 321 ppm)(60) (δ = 238 ppm)

3.1.3 Type (c) Compounds

The ^{77}Se chemical shifts in this type of metal complex do not differ significantly from those of the free ligands unless the selenium is involved in some interaction with the metal atom.

3.2 ^{77}Se Couplings

Coupling constants [$^nJ(\text{X}, ^{77}\text{Se})$] can be extracted quite easily from the spectra of the coupling partner (e.g. ^1H , ^{13}C , ^{31}P , or others) by inspecting the ^{77}Se satellites; each has about 4% intensity compared with the corresponding main signal. These J values have been reviewed extensively,^{5,7,8} so in this article we concentrate on some general outlines.

3.2.1 $^nJ(^{77}\text{Se}, ^1\text{H})$

One-bond coupling constants $^1J(^{77}\text{Se}, ^1\text{H})$ are rather rare in the literature since they require a Se-H fragment in the molecule. Presumably, they are positive, and values between 65.4 (H_2Se) and 38 ± 1 Hz (Bu^tSeH) have been reported.^{5,7} An exception is $\text{Cp-W}(\text{CO}_3)\text{SeH}$ for which $^1J(^{77}\text{Se}, ^1\text{H}) = 5.3$ Hz.⁴⁹ $^2J(^{77}\text{Se}, ^1\text{H})$ values (geminal coupling) are mostly positive. They are between 4 and 16 Hz for hydrogen atoms in aliphatic fragments, but can increase to 50 Hz if the fragment has further geminal heteroatoms or if it is in an aromatic ring (selenophene 47.5 Hz).⁵ Only in molecules in which selenium bears no free electron pairs do the coupling constants become negative, e.g. in MeSeO_3^- , -17.4 Hz.⁵ There seems to be some stereochemical dependence in two-⁵ and in three-bond (vicinal) couplings, $^3J(^{77}\text{Se}, ^1\text{H})$.^{5,52}

3.2.2 $^nJ(^{77}\text{Se}, ^{13}\text{C})$

One-bond couplings ($^1J(^{77}\text{Se}, ^{13}\text{C})$) are negative and strongly depend on the hybridization state of the carbon atom.⁵ Typical ranges are -45 to -100 Hz for $\text{Csp}^3\text{-Se}$ [The values are

larger if heteroatoms are attached to carbon: -90 to -162 Hz for $\text{C}=\text{C-Se}$ (aromatic or alkenic); -203 to -249 Hz for $\text{C}=\text{Se}$; -184 to -193 Hz for $\text{C}\equiv\text{C-Se}$; -240 to -292 Hz for $\text{N}\equiv\text{C-Se}$; -274 Hz for $\text{-N}=\text{C-Se}$; and -287 Hz for $\text{O}=\text{C-Se}$].^{5,32} Exceptionally low values are found for selenonic acids, e.g. -13 Hz for Me-SeO_3^- .⁵ Two-bond couplings [$^2J(^{77}\text{Se}, ^{13}\text{C})$] have not been studied intensively. Generally, they are positive, much smaller than $^1J(^{77}\text{Se}, ^{13}\text{C})$, and rarely larger than 15 Hz for aliphatic carbons. However, values up to 34 Hz have been detected in heteroaromatics,^{5,53} but these cannot be confused with one-bond couplings.⁵ Very little is known about $^3J(^{77}\text{Se}, ^{13}\text{C})$ values. They seem to be in the range 3-12 Hz,^{53,54} but decrease to less than 3 Hz if the selenium atom is oxygenated.⁵³ Further investigation is needed to explore whether a Karplus-type dependence exists.

3.2.3 $^nJ(^{77}\text{Se}, ^{15}\text{N})$

Only two reports on $^{77}\text{Se}-^{15}\text{N}$ couplings seem to exist, and only one-bond coupling constants [$^1J(^{77}\text{Se}, ^{15}\text{N})$] are known: +60.1 Hz for $\text{CF}_3\text{Se-NH}_2$,⁵⁵ 83.4 Hz for (30), 89.8 Hz for (31), and 92.2 Hz for (32).³³

3.2.4 $^nJ(^{77}\text{Se}, ^{19}\text{F})$

One-bond $^{77}\text{Se}-^{19}\text{F}$ coupling constants [$^1J(^{77}\text{Se}, ^{19}\text{F})$] are generally very large and can considerably exceed 1000 Hz. If fluorine atoms are in different stereochemical positions, they can be discerned easily. For example, the coupling to the axial fluorine atom in SeF_4 (trigonal bipyramid) is 284 Hz and that to the equatorial one 1206 Hz.^{5,8} Values between 1200 and 1500 Hz are reached in SeF_6 and related Se(VI) derivatives, but stereochemical differences are much smaller and it is not possible to make reliable assignments on this basis.⁵ $^2J(^{77}\text{Se}, ^{19}\text{F})$ values can be substantial; 120 and 117 Hz have been measured in fluorinated 1,3-diselenetanes, and even four-bond coupling constants of 11 and 12 Hz exist in these molecules.⁵⁶

3.2.5 $^nJ(^{77}\text{Se}, ^{29}\text{Si})$

Few data have been published, and these are exclusively one-bond couplings. The largest is +110.6 Hz for $\text{H}_3\text{Si-Se-SiH}_3$ ⁵ and the smallest is 48.5 Hz for (37).

3.2.6 $^nJ(^{77}\text{Se}, ^{31}\text{P})$

One-bond couplings [$^1J(^{77}\text{Se}, ^{31}\text{P})$] are negative and can have high values.^{5,8} The magnitude of this coupling constant is an excellent indicator of the bond order between phosphorus and selenium. Values between -800 and -1200 Hz are normal for $\text{P}=\text{Se}$ double bonds, whereas the values are much smaller for single bonds (-200 to -620 Hz).^{5,8} Moreover, the coupling constants contain information about the stereochemistry of the compounds investigated. In both pairs (61)/(62) and (63)/(64) the absolute values of the coupling is larger for equatorially positioned selenium atoms,⁵⁷ and this is a general rule.

3.2.7 $^nJ(^{77}\text{Se}, ^{77}\text{Se})$

^{77}Se – ^{77}Se couplings have not received much attention as their observation requires compounds with at least two selenium atoms in unsymmetrical positions. One-bond couplings have been measured for a number of diselenides and δ values between +22 Hz (Ph-Se-Se-Me)⁷ and –66.5 Hz ($\text{CF}_2\text{Cl-Se-Se-CF}_2\text{Cl}$)⁵⁸ have been found. $^1J(^{77}\text{Se}, ^{77}\text{Se})$ values in various polyselenide anions are 250 ± 20 Hz if a charged selenium atom is involved.⁵⁹ Neutral cyclic sulfur–selenium compounds, however, have much smaller values (–17 to –65 Hz).^{24a,60} The largest one-bond ^{77}Se – ^{77}Se coupling so far reported seems to be 391 Hz (sign unknown) for (65).⁶¹ Two-bond couplings can adopt large values. In cyclic sulfur–selenium compounds their absolute values are even larger than $^1J(^{77}\text{Se}, ^{77}\text{Se})$: 95–114 Hz.^{24a,60} In the same class of compounds three-bond couplings are noticeable (3–16 Hz).^{24a,60} An interesting case of a clear stereochemical differentiation by means of $^3J(^{77}\text{Se}, ^{77}\text{Se})$ values is for the pair (66) and (67).⁵² Four-bond couplings vary between 0 and 16 Hz in sulfur–selenium cycles.^{24a,60}

3.2.8 $^nJ(^{125}\text{Te}, ^{77}\text{Se})$

One-bond couplings have been reported for Me-Se-Te-Me (–169 Hz)⁵ and some polychalcogen cations and anions, for which the values can be substantial (189–670 Hz).^{5,8} In compound (68) a very strong coupling between selenium and tellurium indicates the existence of a transannular interaction between these atoms.⁶²

3.2.9 $^nJ(^{129}\text{Xe}, ^{77}\text{Se})$

A two-bond coupling to ^{129}Xe has been reported for $\text{Xe}(\text{OSeF}_5)_2$ (153.8 Hz).⁶³

3.2.10 Couplings to Metal Nuclei

One-bond couplings to ^{119}Sn are generally between 500 and 1700 Hz,⁵ whereas the two reported ^{207}Pb – ^{77}Se couplings are

780 Hz ($\text{Ph}_3\text{Pb-Se-PbPh}_3$)⁴⁵ and 149 Hz ($\text{K}_2\text{Pb}_2\text{Se}_3$).⁶⁴ Typical couplings to transition metals^{5,8} are: ^{103}Rh , 20–44 Hz;⁶⁵ ^{113}Cd , 126–195 Hz; ^{183}W , 14–109 Hz;^{46,66} ^{195}Pt , 74–630 Hz; and ^{199}Hg , –751 to –1270 Hz. Strong diagnostic dependences of $^1J(^{195}\text{Pt}, ^{77}\text{Se})$ on the substituents and the stereochemistry have been noted.^{5,8}

3.3 Special NMR Techniques and Applications

Conformational analysis of selenium-containing compounds by variable temperature NMR spectroscopy (DNMR) is facilitated by the high sensitivity of ^{77}Se chemical shifts because the coalescence temperature is generally much higher than in ^1H or ^{13}C NMR spectra. For example, the coalescence of ^{77}Se signals for the ring inversion process of phenylselenenylcyclohexane occurs at about 10 °C, whereas that of ^1H or ^{13}C signals appears at least 60 °C lower at the same external field strength.^{11a,67} Analyses of other molecular systems such as 2,11-diselena[3.3]metacyclopentane,⁶⁸ [3.3]diselena- and [4.4]tetraselenacyclopentanes,⁶⁹ and 1,4,5,7-tetrahydro-3H-2,6-benzodiselenines⁷⁰ have been undertaken. The study of 2-arylseleno-1,3-dithianes shed some light on the question of an anomeric effect of arylselenenyl substituents.⁷¹

Gronowitz and coworkers⁷² were the first to report that ^{77}Se NMR is an excellent tool for chiral recognition. They found noticeable differences in the spectra of diastereomeric α -phenylselenenylpropionic esters.²⁷ In 1990, the first derivatizing agent, (4*S*,5*R*)-(–)-4-methyl-5-phenyloxazolidine-2-selone (69), for the determination of enantiomeric purities by ^{77}Se NMR was published.⁷³ The authors showed that the ^{77}Se signal is split into two with a separation of 5.3 Hz (external field 7.05 T) when (69) was reacted with the racemic mixture of 5-methylheptanoic acid to produce (70) (Scheme 1). This is a chiral recognition across seven bonds. Moreover, the presence of deuterium five bonds away from the selenium atom (71), could clearly be recognized by a deuterium isotope shift.^{73a}

High-resolution solid state CP MAS ^{77}Se NMR has been applied to some selenium-containing molecules. The ^{77}Se chemical shift tensors σ_{11} , σ_{22} , and σ_{33} of a number of inorganic and organic compounds have been determined and their isotropic shifts δ_{iso} compared with the chemical shifts in liquid or solution δ .⁷⁴ It was found that δ and δ_{iso} are rather similar but in some cases there is more than one signal,

due to crystallographic nonequivalences in the unit cell. So, for example, selenourea $[(\text{NH}_2)_2\text{C}=\text{Se}]$ gives five lines spread over a range of 36 ppm.⁷⁴ Two signals have been recorded for the cyclic $(\text{Me}_2\text{SnSe})_3$, $\delta = -266$ ppm [$^1J(^{119}\text{Sn}, ^{77}\text{Se}) = 1191$] and $\delta = -352$ ppm [$^1J(^{119}\text{Sn}, ^{77}\text{Se}) = 1264$], with an intensity ratio of 1 : 2, indicating that the molecule adopts a twist-boat conformation with a two-fold symmetry axis.⁷⁵ The results of CP MAS NMR spectra of tetra- and hexaselenacoronands with 12-, 16-, 18-, and 24-membered rings have been compared with X-ray structures and discussed in terms of conformational properties.⁷⁶ Some borylselenides⁷⁷ and Ag_7PSe_6 ⁷⁸ have also been studied by means of MAS ^{77}Se NMR.

4 ^{125}Te NMR AND ITS APPLICATIONS

4.1 ^{125}Te Chemical Shifts

The total range of ^{125}Te chemical shifts is nearly 5000 ppm. The data for some selected compounds are compiled in Table 5.^{4–9} Novel inorganic anions with high coordination numbers have recently been introduced, e.g. TeF_7^- ($\delta = 327$ ppm, Table 5) which has a pentagonal bipyramidal structure.⁷⁹ TeF_5Cl and some of its hydrolysis products have also been investigated (Table 5).⁸⁰ Other tellurium compounds with six ligands, three phenyl groups, and three halogens, resonate between $\delta = 776$ and 896 ppm.⁸¹ The ^{125}Te chemical shifts of dithiotellurides $[\text{Te}(\text{SR})_2]$, R = alkyl or Ph are between $\delta = 63$ and 749 ppm (Table 5).⁸²

Table 5 contains the ^{125}Te chemical shifts of basic dialkyl, alkylaryl, and diaryl tellurides, and ditellurides; more detailed information about the effects of various of these substituents may be obtained from the extensive compilations given by Luthra and Odom.⁷ Since, in contrast to the diselenides, diorganyl ditellurides have a tendency to undergo exchange reactions, a number of unsymmetrical derivatives have been studied.^{7,83} The effects of replacing α -hydrogen atoms of dimethyl telluride and phenylmethyl tellurides or ditellurides are in close analogy to those seen with the corresponding selenides. An example is shown in Figure 3, correlation (a).⁸⁴ The two other correlations in Figure 3 reveal that the same holds for diorganyltellurium dichlorides (b) and difluorides (c), although the magnitudes of the substituent effects decrease gradually.^{11b}

Similarly, ^{125}Te chemical shifts in *ortho*-substituted tellurophenetols can be correlated with analogous selenophenetols.⁸⁵ Lithium salts of tellurocarboxylates $[\text{R}-\text{C}(=\text{O})-\text{Te}^-\text{Li}^+]$ have been described.⁸⁶ The ^{125}Te chemical shifts of bis(alkyltelluro)ethynes $(\text{R}-\text{Te}-\text{C}\equiv\text{C}-\text{Te}-\text{R})$ are $\delta = 215$ (R = Me) and 404 ppm (R = Et).⁸⁷ Bis(organyltelluro)methanes $(\text{R}-\text{Te}-\text{CH}_2-\text{Te}-\text{R})$, R = alkyl or Ph and their halide derivatives have been described, and the substituent effects of alkyl groups were determined.⁸⁸

Hypervalent tellurium compounds with organic ligands have been described recently: Me_4Te and $(\text{H}_2\text{C}=\text{CH})_4\text{Te}$,⁸⁹ triarylate complexes Ar_3Te^- ,⁹⁰ triaryltelluronium cations Ar_3Te^+ (Table 5),⁹¹ and some aromatic compounds with structures analogous to the selenium compounds (38) and (39), for example Ph_4Te , ($\delta = 509$ ppm).⁹¹

Halogenation of tellurium to diorganyltellurium dihalides $[\text{R}-\text{Te}(\text{Hal})_2-\text{R}]$ and organyltellurium trihalides $(\text{R}-\text{TeHal}_3)$ ⁹²

Figure 3 ^{125}Te chemical shifts of some alkanes substituted with three different kinds of tellurium functionalities plotted against ^{77}Se chemical shifts of corresponding selenium analogs ($\text{PhSe}-\text{R}^{84}$): (a) $\text{PhTe}-\text{R}^{84}$, (b) $\text{PhTe}(\text{Cl}_2)-\text{R}$, (c) $\text{PhTe}(\text{F}_2)-\text{R}$. For better comparability the ^{125}Te chemical shifts are referred to the methyl derivative (R = Me) in each series. In order not to confuse these values with ^{125}Te chemical shifts, the symbol $\Delta(^{125}\text{Te})$ is used

leads to substantial deshieldings, and large solvent shifts have been noticed in this class of compounds which, at least in part, may be due to the formation of dimers.⁷ The first aliphatic tellurenyl halogenides reported are $(\text{Me}_3\text{Si})_3\text{C}-\text{Te}-\text{X}$ with X = Cl ($\delta = 1693$ ppm), X = Br ($\delta = 1347$ ppm), and X = I ($\delta = 1185$ ppm).⁹³

^{125}Te chemical shifts of phosphine tellurides (tellurophosphoranes, R_3PTe) are between $\delta = -513$ (R = Me) and -1000 ppm (R = Pr^i) and have been interpreted in terms of bond characters within the P–Te bond.⁹⁴

Recently, the first stable telluroketone (72) has been reported, and, as expected, its chemical shift ($\delta = 2858$ ppm) is one of the highest ever recorded in a neutral organotellurium compound.⁹⁵ If one heteroatom is attached to the tellurocarbonyl group, the chemical shift is considerably smaller; for example, (73) ($\delta = 1418$ ppm).⁹⁶ The 2-telluroimidazoline (74) has an unusually high shielding ($\delta = -168$ ppm), and this has been ascribed to a considerable contribution of the dipolar canonical form.⁹⁷

Many cyclic tellurium compounds have been summarized previously.^{5,7,9} Similar to the trends shown by the selenium analogs, the ^{125}Te chemical shift of benzo[*b*]tellurophene (76, $\delta = 727$ ppm) is significantly smaller than that of tellurophene (75, $\delta = 782$ ppm). Halogenation of the tellurium atom in

Te^{2-}	-1748	Me_4Te	-67
		$(\text{CH}_2=\text{CH})_4\text{Te}$	412

^aDifferent chemical shift values are from different literature sources and might be due to medium effects.

(77) is accompanied by a strong deshielding; the higher the electronegativity of the halogen, the larger the ^{125}Te chemical shift; compare (78)–(81). Replacement of the methylene group in (82) by oxygen (83), tellurium (84), or C=O (85) results in large chemical shift alterations. Some tellurapyran derivatives [(86)–(88)] have been reported.⁹⁸ The oxidation of (89) results in a bicyclic dication (90) associated with an enormous deshielding of the tellurium atoms.⁹⁹

During recent years, many papers dealing with tellurium-containing metal complexes have appeared. Only two, arbitrarily chosen examples are discussed here. The stereoisomeric platinum complexes (91) and (92) differ in their ^{125}Te chemical shifts; however, it was shown in a series of related platinum and palladium complexes with Me_2Te or Ph_2Te and Cl, Br, or I that, in contrast to the ^{125}Te – ^{195}Pt coupling constants (see below), the ^{125}Te chemical shift is not a safe indicator of the isomerism.¹⁰⁰ The first example of a complex with a terminal transition metal–tellurium double bond reported in the literature is (93), which has a remarkably large $\delta(^{125}\text{Te})$ value.¹⁰¹

4.2 ^{125}Te Coupling Constants

^{125}Te coupling constants are much less abundant in the literature than those involving ^{77}Se , and mostly they are associated with one-bond couplings. Assuming that scalar

couplings involving ^{125}Te and ^{77}Se are both governed by the Fermi contact interaction, it can be expected that $^{125}\text{Te}-\text{X}$ coupling constants are approximately two times larger than the corresponding $^{77}\text{Se}-\text{X}$ coupling constants. Due to the negative magnetogyric ratio of ^{125}Te , the signs of the respective J values should be opposite (unless their magnitudes are small).⁵ In fact, the ratio $J(^{125}\text{Te},\text{X})/J(^{77}\text{Se},\text{X})$ is 2–3 (in absolute value).^{5,7}

4.2.1 $^nJ(^{125}\text{Te}, ^1\text{H})$

One-bond coupling constants [$^1J(^{125}\text{Te}, ^1\text{H})$] are negative; e.g. –59 Hz for H_2Te .⁵ $^2J(^{125}\text{Te}, ^1\text{H})$ in dialkyl tellurides are approximately –20 Hz, but larger if tellurium is incorporated in a heteroaromatic (tellurophene –90 Hz) or in tellurium dihalides (–40 Hz).⁵ $^3J(^{125}\text{Te}, ^1\text{H})$ values are smaller, but still significant: Et_2Te , –22.7 Hz; and tellurophene, –12 Hz.⁵

4.2.2 $^nJ(^{125}\text{Te}, ^{13}\text{C})$

One-bond coupling constants [$^1J(^{125}\text{Te}, ^{13}\text{C})$] are positive and show a strong dependence on the hybridization state of the carbon atom involved. Examples are: Me_2Te , 162 Hz; $(\text{H}_2\text{C}=\text{CH})_2\text{Te}$, 285 Hz; and $\text{Me}-\text{Te}-\text{C}\equiv\text{C}-\text{Bu}$, 531 Hz.⁶

4.2.3 $^1J(^{125}\text{Te}, ^{19}\text{F})$

Very large (probably positive) values have been noticed, for example: TeF_6 , 3688 Hz; $(\text{HO})_5\text{TeF}$, 2754 Hz;⁵ TeF_5Cl , 3601/3444 Hz;⁸⁰ and TeF_7^- , 2876 Hz.⁷⁹ In some diorganyl-tellurium difluorides, $(\text{Ph}-\text{TeF}_2-\text{R})$, values between 695 and 735 Hz have been observed.^{11b} If R is chiral, the two fluorine atoms are diastereotopic and differ considerably in their ^{19}F chemical shifts and $^1J(^{125}\text{Te}, ^{19}\text{F})$ values.^{11b} In Ph_2TeF_2 , the $^1J(^{125}\text{Te}, ^{19}\text{F})$ coupling is only 530 Hz.^{11b}

4.2.4 $^1J(^{125}\text{Te}, ^{31}\text{P})$

These couplings are assumed to be positive, and their value depends strongly on the bond order: in compounds $\text{R}_3\text{P}=\text{Te}$ they are 1548–1743 Hz;^{5,94} whereas they are much smaller in compounds like $(\text{Bu}^t)_2\text{P}-\text{Te}-\text{P}(\text{Bu}^t)_2$ (451 Hz).⁵

4.2.5 $^1J(^{125}\text{Te}, ^{77}\text{Se})$

These couplings have been discussed in Section 3.2.8.

4.2.6 $^1J(^{125}\text{Te}, ^{123}\text{Te})$

These couplings have been recorded occasionally in compounds with more than one tellurium atom, e.g. in polyatomic cations (600–1200 Hz) and diorganyl ditellurides (213–269 Hz).⁵

4.2.7 $^1J(^{183}\text{W}, ^{125}\text{Te})$

The one-bond $^{183}\text{W}-^{125}\text{Te}$ coupling constant in (93) is 190 Hz.¹⁰¹

4.2.8 $^1J(^{195}\text{Pt}, ^{125}\text{Te})$

In platinum complexes the one-bond $^{195}\text{Pt}-^{125}\text{Te}$ coupling constants are often strongly dependent on the stereochemistry.⁵

For example, a value of 824 Hz was found for the *cis* isomer (91), whereas that of the *trans* isomer (92) is 489 Hz.¹⁰⁰ This sequence seems to be a rule, and the large differences in their magnitudes allow stereochemical assignments.

More ^{125}Te coupling data are given by Rodger et al.,⁴ McFarlane and McFarlane,⁵ and Luthra and Odum.⁷

4.3 Special NMR Techniques and Applications

Temperature-variable ^{125}Te NMR (DNMR) of phenyltellurenyl-substituted cyclohexane and related derivatives showed that the coalescence temperature associated with the ring inversion is even higher than in ^{77}Se DNMR of analogous selenides.¹¹ The ^{125}Te chemical shift difference in the axial and the equatorial phenyltellurenylcyclohexane (at –30 °C) is 130 ppm.¹¹

Only a very few stereochemical applications of ^{125}Te NMR spectroscopy have been published. The stereoisomeric bicyclic compounds (94) and (95) differ by 34 ppm in their ^{125}Te chemical shifts.⁷ The difference in the chemical shifts of the two diastereomeric camphor derivatives (96) and (97) is much larger (177 ppm).¹⁰² In spite of the rather long distance from the menthyl residue in (98)–(100), the tellurium atom is able to reflect differential stereochemical positions of the vicinal methyl group by a ^{125}Te chemical shift difference of 5–7 ppm.^{11b} This allows one to conclude that tellurium is an excellent nucleus for chiral recognition.

Little is known about solid state CP MAS ^{125}Te NMR spectroscopy. In a pioneering paper, it has been shown that $\text{Te}(\text{OH})_6$ has two resonances, $\delta_{\text{iso}} = 692$ and 686 ppm, reflecting the great sensitivity of this method to even minor distortions from the octahedral symmetry in the monoclinic crystal.¹⁰³ Surprisingly, the scalar coupling of ^{125}Te to two equivalent chlorine atoms [$^1J(^{125}\text{Te}, ^{35}\text{Cl}) = 106 \pm 5$ Hz] could be detected in the solid state CP MAS ^{125}Te NMR spectrum of $\text{Me}_3\text{TeCl}\cdot\text{H}_2\text{O}$.¹⁰³ In a series of salts with Me_3Te^+ and Ph_3Te^+ cations it was demonstrated that there are long-range covalent interactions between these cations and their anions (Cl^- , I^- , and NO_3^-).¹⁰⁴

1 INTRODUCTION

During the decade following the landmark papers of Bloch et al.¹ and Purcell et al.² NMR experiments were performed with about 30 elements in the solid, liquid, or gas phase. One of the elements studied during this early development period of NMR spectroscopy was thallium. By 1953, solid³ and liquid⁴ state spectra had been obtained for the thallium nucleus. The availability of high-field magnets, multinuclear spectrometers, pulsed Fourier transform techniques, and an expanded chemistry have caused a 'rediscovery' of this element.

The nuclear properties of thallium and the sensitivity of the NMR parameters, chemical shift, spin-spin coupling constant, and relaxation time to the chemical environment into which the element is placed make thallium well suited for the NMR experiment and an excellent probe for studying a variety of chemical and physical phenomena. The intent of this review is not to present an extensive survey of thallium NMR spectroscopy but to emphasize the general characteristics of thallium NMR spectroscopy with selected applications to the solid and liquid states. An extensive review of the thallium NMR literature has been published previously.⁵

2 GENERAL CHARACTERISTICS

Because of their intrinsic nuclear properties, both isotopes of thallium are well suited for NMR experiments. Thallium-205 (70.5% natural abundance) and ²⁰³Tl (29.5% natural abundance) have spins of $I = \frac{1}{2}$. The magnetic moments (μ/μ_N) for ²⁰⁵Tl and ²⁰³Tl are 2.7914 and 2.7646, respectively. The resonance frequencies of ²⁰⁵Tl at a magnet field strength of 11.75 T, 7.05 T, and 2.3488 T are 288.474 MHz, 173.108 MHz, and 57.708 MHz, respectively. For the ²⁰³Tl nucleus the resonance frequencies at the same magnetic field strengths are 285.805 MHz, 171.506 MHz, and 57.149 MHz. The relative receptivity of the more abundant isotope, ²⁰⁵Tl, is 0.1355 with respect to the proton which is assigned a value of 1. This makes the ²⁰⁵Tl nucleus the fourth most receptive spin $I = \frac{1}{2}$ nuclide. The very high receptivity of both ²⁰⁵Tl and ²⁰³Tl nuclei allows them to be directly observed with very little difficulty. Spectra of ²⁰⁵Tl in solution can be obtained from samples with thallium concentrations in the submillimolar range.

Although the variety of thallium compounds is not as extensive as that of other metals, such as cobalt, the available oxidation states of (I) and (III) provide an interesting array of electronic environments for thallium and concomitant chemical shift groupings. For example, the resonance frequency of Tl(III) is normally higher than that of Tl(I). The chemical shift range of thallium is extremely large, covering approximately 7000 ppm for Tl(III) species and over 3400 ppm for Tl(I) species. The origin of this large chemical shift range lies within the paramagnetic term of the nuclear screening constant. The total diamagnetic shielding of the thallium atom is quite appreciable, being about 10 000 ppm. However, in chemical bonding the core electrons are relatively unperturbed, the valence electrons being most affected. Therefore, the important quantity in determining the chemical shift is not the total shielding but the shielding per valence electron. For thallium, the diamagnetic contribution per valence electron is of the order of 10–250 ppm. This is relatively small compared with the observed chemical shift range of approximately 7000 ppm. This means that the paramagnetic term must be responsible for about 90% of the variation observed in the thallium chemical shift. A value of 5550 ppm for the paramagnetic term has been obtained for the linear dimethylthallium cation.⁶

Whereas the ⁵⁹Co nucleus, with a chemical shift range of 18 000 ppm, appears to be more sensitive to electronic effects than ²⁰⁵Tl, the greater chemical shift range of ²⁰⁵Tl in compounds in which Co and Tl are in similar environments suggests that ²⁰⁵Tl has the greatest NMR 'shiftability' of all the elements. The magnitude of this chemical shift range can be appreciated from a consideration of the solvent, phase change, substituent change, and temperature effects on the ²⁰⁵Tl chemical shift. The chemical shift of the ²⁰⁵Tl(I) ion increases by about 2000 ppm as the solvent is changed from water to liquid ammonia. The chemical shift of Me₂TlNO₃ increases by 240 ppm as the solvent is changed from hexamethylphosphoramide to *n*-butylamine. The effect of environmental alteration, by phase change, on the chemical shift can also be equally dramatic. For example, the chemical shift of TlCl increases by 925 ppm in progressing from the melt to the solid phase. Substituent changes produce large chemical shifts: (1) the difference in chemical shift between TlCl_{solid} and TlI_{solid} is 920 ppm; (2) the difference in chemical shift between Me₃Tl and Et₃Tl is 130 ppm and; (3) the chemical shifts of C₆H₅Tl(TFA)₂, 4-Bu^tC₆H₄Tl(TFA)₂, 4-PrⁱC₆H₄Tl(TFA)₂ and 4-PrⁿC₆H₄Tl(TFA)₂ (where TFA = trifluoroacetic acid) are +2790 ppm, +2818 ppm, +2823, and +2816 ppm, respectively. The chemical shift can also be very temperature dependent, as illustrated by the fact that, in liquid methylamine solutions, the resonance frequency of the Tl(I) ion changes at 5 ppm K⁻¹. The temperature dependence of the ²⁰⁵Tl resonance frequency of the dimethylthallium cation in aqueous solution has been shown to be an accurate, convenient thermometer for determining the temperature of samples within the magnetic field of an NMR spectrometer.⁷ These examples serve to illustrate the fact that the ²⁰⁵Tl chemical shift is an exquisitely sensitive probe for subtle changes in environment. This feature of the NMR properties of ²⁰⁵Tl makes it quite useful for investigating such phenomena as ion-pairing, solvent-solute interaction, phase changes, long-range substituent effects, and binding constants.

The chemical shift anisotropy has been measured for the ²⁰⁵Tl nucleus in a number of chemical environments. The

values extend from 55 ppm for 7.5% TlNO_3 in KNO_3 to 5550 ppm for Me_2TlBr . Again, the magnitude of this range of this chemical shift property epitomizes the sensitivity of the ^{205}Tl nucleus to the chemical environment in which it is placed.

Just as the ^{205}Tl nucleus exhibits a large chemical shift range, the range in magnitude of the spin–spin coupling constants involving this nucleus is also very large. For example, $^1J(^{205}\text{Tl}, ^{31}\text{P}) = 3203 \text{ Hz}$, $^1J(^{205}\text{Tl}, ^{13}\text{C}) > 10\,000 \text{ Hz}$, and $^1J(^{205}\text{Tl}, ^1\text{H}) = 6144 \text{ Hz}$. Long-range coupling constants $^{\text{Sor6}}J(^{205}\text{Tl}, ^1\text{H})$ can be about 100 Hz. Substituent effects are very pronounced. For example, $^2J(^{205}\text{Tl}, ^1\text{H})$ changes by 70 Hz if the methyl groups in Me_3Tl are replaced by ethyl groups and the $^1J(^{205}\text{Tl}, ^{13}\text{C})$ coupling constant changes from 10 718 Hz in $\text{C}_6\text{H}_5\text{Tl}(\text{OAc})_2$ to 8841 Hz in $2,4,6\text{-Me}_3\text{PhTl}(\text{OAc})_2$. The effect of change in isotope from ^{205}Tl to ^{203}Tl can also be observed. The ^{203}Tl coupling constants are less than those of ^{205}Tl [$^3J(^{205}\text{Tl}, ^1\text{H}) = 387 \text{ Hz}$ and $^3J(^{203}\text{Tl}, ^1\text{H}) = 384 \text{ Hz}$ in the compound, $\text{TlN}(\text{CH}_2\text{CO}_2^-)_3$], as dictated by the difference in magnetogyric ratio. Thallium coupling constants can also be solvent- and temperature-dependent. The value of $^2J(^{205}\text{Tl}, ^1\text{H})$ for Me_3Tl in acetone is -268.8 Hz and -250.8 Hz when CH_2Cl_2 is the solvent. The value of $^2J(^{205}\text{Tl}, ^1\text{H})$ for Me_3Tl dissolved in CH_2Cl_2 at -30°C , -50°C , and -70°C is -232.8 Hz , -243 Hz , and -250.8 Hz , respectively. Because of the highly ionic nature of Tl(I) complexes, few coupling constants have been observed for this oxidation state. An example of spin–spin coupling with Tl(I) is found in the Tl(I) –valinomycin complex where $^2J(^{205}\text{Tl}, ^{13}\text{C}) = 96$ and 101 Hz .⁸ The large coupling constants associated with thallium NMR spectroscopy can, in some instances, present experimental problems because of insufficiently large spectral window, aliased peaks, and computer-limited resolution. In the observation of nuclei to which thallium is coupled, it must be remembered that there are two isotopes and that decoupling of one might still leave a relatively complex spectrum.

Several linewidth and relaxation studies have been conducted on ^{205}Tl and ^{203}Tl in the solid state. Because ^{205}Tl and ^{203}Tl nuclides have large magnetogyric ratios, direct dipole–dipole interaction is expected to contribute significantly to the NMR linewidths of these nuclides. The solid state spectra of thallium frequently exhibit line broadening as the result of indirect spin–spin coupling. This spin–spin interaction is independent of the magnetic field but depends on the transmission of nuclear spin information directly through intervening electrons. Although the indirect coupling may be negligible for light nuclides, the large hyperfine interaction is an important source of line broadening in many cases for thallium. The ^{205}Tl and ^{203}Tl linewidths of thallium metal and Tl_2O as a function of the percentage of abundance of ^{205}Tl have been investigated.⁹ It was found that the ^{205}Tl line was relatively narrow in highly enriched ^{205}Tl samples, whereas the ^{203}Tl line was broad. The opposite effect was observed with samples enriched with ^{203}Tl . It was concluded that spin exchange between unlike nuclei (^{205}Tl and ^{203}Tl) contributes to the second moment or the linewidth, while spin exchange between like nuclei (^{205}Tl and ^{205}Tl or ^{203}Tl and ^{203}Tl) does not affect the second moment. One, therefore, has a very good method for detecting the contribution to the second moment or line broadening from exchange interaction in samples containing thallium at the natural abundance level. Because ^{203}Tl ,

whose natural abundance is 29.5%, is surrounded primarily by the unlike ^{205}Tl nucleus in the solid, exchange interactions, if present, broaden this line more than the line of ^{205}Tl which is surrounded primarily by other ^{205}Tl nuclei. The favorable natural abundance and magnetogyric ratio of ^{205}Tl make this a simple and effective method for detecting the presence of exchange broadening.

Line broadening resulting primarily from exchange interactions frequently prevents one from observing the chemical shift anisotropy (CSA) in the powder spectrum of thallium compounds. One method of eliminating this line-broadening mechanism is by dilution of the spin of interest in a magnetically inert matrix. An example of this technique can be illustrated with solid TlNO_3 . Since the main source of line broadening in pure TlNO_3 arises from spin exchange between Tl(I) ions, the dilution of TlNO_3 in a matrix of KNO_3 should produce significant line narrowing of the thallium resonance line due to the presence of the small magnetic moments of the potassium nuclides.

In solution, the spin–lattice relaxation time of the Tl(I) ion has been found to be very sensitive to environmental effects. In an aqueous solution the spin–lattice relaxation time for the Tl(I) ion changes from 1.8 s in the absence of dissolved oxygen to 0.024 s in the presence of 101.3 kPa (1 atm) of oxygen.¹⁰ This dependence of relaxation time upon oxygen can be advantageous because it permits faster pulsing and, therefore, more rapid spectral accumulation. The spin–lattice relaxation time of the Tl(I) ion is also solvent-dependent.¹¹ In aqueous solution, the Tl(I) spin–lattice relaxation time is dominated by the spin–rotation mechanism.^{10,12} The $^{205}\text{Tl(I)}$ and $^{203}\text{Tl(I)}$ relaxation times are equal and are independent of solvent isotopic substitution (H_2O , D_2O), concentration (0.03–2.0 M), anion, and resonance frequency.^{10,12} However, in nonaqueous solution the spin–lattice relaxation time of Tl(I) can be very dependent upon the CSA mechanism.¹³ In the case of Tl(I) –antibiotic complexes, the spin–lattice relaxation time is determined by contributions from spin–rotation, dipolar, and CSA mechanisms.^{14–16}

An excellent study of the relaxation of the $(\text{CH}_3)_2\text{Tl}^+$ cation as a function of temperature and magnetic field strength has been published.¹⁷ Although the relaxation is dominated by the CSA mechanism, a contribution from the spin–rotation mechanism was also found to be present. Activation energies for the reorientational correlation time and the angular momentum correlation time were determined to be 19.7 kJ mol^{-1} and 17.7 kJ mol^{-1} , respectively. At 298 K, the reorientational correlation time was found to be 39.1 ps and a value of $5.05 \times 10^{-15} \text{ s}$ was obtained for the angular momentum correlation time. The ^{205}Tl spin–lattice relaxation time of the $(\text{CH}_3)_2\text{Tl}^+$ cation in an aqueous glycerol solution has been studied as a function of temperature and magnetic field strength. In this solution medium, the CSA relaxation mechanism was the only effective relaxation mechanism.¹⁸ Theoretical investigations of the importance of the CSA and spin–rotation mechanisms¹⁹ and other mechanisms²⁰ for thallium relaxation have been made. The spin–lattice relaxation time of the $(\text{CH}_3)_2\text{Tl}^+$ cation is sensitive to the presence of oxygen in solution, however, this dependence is not as great as that found for the Tl(I) cation.¹⁰

3 CHEMICAL APPLICATIONS

One of the most fundamental types of solution systems to be investigated involves the interaction between a thallium ion, Tl(I) or Tl(III), and a single type of solvent molecule. In practice, this type of investigation can be very difficult due to the proclivity of the thallium ion to form ion-pairs or higher order aggregates. To eliminate this problem, one must obtain the infinite dilution chemical shift of the ion from an extrapolation to infinite dilution of the curve representing the relationship between the chemical shift and ion concentration. The extreme sensitivity of the thallium chemical shift to the chemical and physical environment means that one must exercise the utmost care in temperature control of the NMR probe, the solvent purity, and the determination of the ionic concentration. For a given solvent, it is advisable to use several thallium salts whose anions are different to approach the infinite dilution point from more than one position on the chemical shift–concentration curve. A computer analysis of the curves can then be used to determine the infinite dilution chemical shift for a solvent.

The ion-pair formation constant (K_{ip}) for a process such as $(\text{Ti}^+ + \text{X}^- \rightleftharpoons \text{Ti}^+\text{X}^-)$ can be determined from the thallium chemical shift–salt concentration relationship. The value of K_{ip} has been determined for a number of solvents²¹ and found to increase with decreasing dielectric constant of the solvent. A correlation between the infinite dilution chemical shift of the Tl(I) ion and the Gutman donor number, a measure of the basicity of the solvent, has been made for a number of solvents.²² This relationship suggests that the more basic the solvent, the higher the resonance frequency of the Tl(I) ion. The increase in resonance frequency with increasing solvent basicity may be interpreted as a measure of the strength of the interaction between the ion and the solvent molecules, with the solvent acting as a Lewis base and interacting both covalently and electrostatically with ions. Transient orbital mixing created by ion–solvent collision-induced polarization of the ion electron cloud may also contribute to the observed change in resonance frequency.

The thermodynamic parameters for the ion-pairing process, ΔH and ΔS , can also be determined by obtaining K_{ip} as a function of temperature.²³ The anion and concentration dependence of the Tl(I) chemical shift in aqueous solution and in nonaqueous solvents^{4,24–37} has been extensively investigated, and chemical shift changes of 10–100 ppm observed. The exceptional dependence of the Tl(I) chemical shift on solvent makes thallium NMR spectroscopy a very good probe for the study of preferential solvation in mixed solvent systems. The chemical shift of 5 mM TlNO_3 in nine binary solvent systems has been analyzed using a nonstatistical distribution of solvate species to describe preferential solvation.^{38–42} Thallium chemical shift, spin–spin coupling and spin–lattice relaxation time studies of Tl(I) complexes with crown ethers^{14–16,28,43–48} and cryptands^{46–48} have been used to obtain information concerning ion–ligand binding and solution structure of these complexes.

Although the Tl(III) ion tends to hydrolyze in aqueous solution, a number of $^{205}\text{Tl(III)}$ NMR investigations, many involving ligand exchange kinetics, have been conducted.^{4,25,49–53} A combination of solution and solid state ^{205}Tl NMR experiments have been used to study the formation and geometry of $(\text{TlX}_n)^{3-n}$ complexes, where $\text{X} = \text{Cl}, \text{Br}$.⁵⁰ Stability constants

and the chemical shifts of the individual species were also determined. This study emphasizes the importance of using solid state NMR data to understand solution results better. The chemical shift range for pH, concentration, and anion effects is about 2000 ppm. Although no specific spin–lattice relaxation time measurements have been made with the Tl(III) ion, a number of linewidths have been reported for nondegassed solution and they range from 10 to 5000 Hz.^{49,50} The measurement of $^{205}\text{Tl(III)}$ NMR linewidths were used to study the kinetics of ligand exchange in the $\text{TlCl}_3\text{--HClO}_4$ (3 M) system.⁵² Rate constants were obtained and the activation energy parameters for the dissociatively activated and associatively activated interchange processes determined.

The concentration, anion, temperature, and solvent dependences of the NMR parameters of the monomethyl and dimethylthallium(III) cations have been investigated. In general, the temperature dependence of the chemical shift is greater than that resulting from changes in anion or concentration for the compounds, $(\text{CH}_3)_2\text{TlX}$ ($\text{X} = \text{NO}_3, \text{BF}_4, \text{O}_2\text{CCH}_3$). For a number of the $(\text{CH}_3)_2\text{Tl(III)}$ derivatives, a linear correlation was observed between the ^{205}Tl chemical shift and the Drago solvent base parameters.⁵⁴ Solvent isotope effects on the chemical shift of the $(\text{CH}_3)_2\text{Tl(III)}$ cation in H_2O and D_2O have been found to be concentration-dependent.¹⁰ Thallium chemical shifts have been obtained for phenylthallium(III) dichloride and its complexes with PPh_3 and dipyrindine in methanol and pyridine,²⁵ diphenylthallium(III) chloride in liquid ammonia,⁵⁵ diphenylthallium(III) bromide in dimethyl sulfoxide,²⁵ a series of substituted arylthallium(III) bis(trifluoroacetates) in a number of solvents,⁵⁶ and triphenylthallium(III) in diethyl ether.²⁵ In general, the diaryls resonate at approximately 200 ppm to high frequency (low field) of the monoaryls and approximately 600 ppm to low frequency of the triaryls.

A proton NMR investigation of the Tl(III) complex with the nitrilotriacetate ion revealed a difference in ^{205}Tl and ^{203}Tl spin–spin coupling constants with the methylene protons, $^{205}\text{Tl}\text{--}^1\text{H} = 387 \text{ Hz}$ and $^{203}\text{Tl}\text{--}^1\text{H} = 384 \text{ Hz}$.

In 1953, 7 years after the papers of Bloch et al.¹ and Purcell et al.,² the first solid state thallium NMR paper was published.³ The types of compounds studied by solid state thallium NMR spectroscopy range from simple inorganic salts, to thallium antibiotic complexes, thallium species contained within zeolites, and high-temperature superconductors.

The dominant factors that determine the chemical shift of the thallium nucleus are oxidation state and electronic interactions with the environment. In solids, the presence of greater covalency might be expected to result in large shifts to high frequency of solvated, ionic thallium species. This has been observed in a number of cases: however, this is in no way an inviolable rule since the thallium resonance in a crystalline salt may be shifted to low frequency of that in solution by several hundred ppm. The relative shifts are determined by the strength of the electronic interactions in the solid compared with those in solution, which may be substantial. Within a series of solids, the highly ionic systems exhibit low-frequency shifts while more covalent systems have resonances at higher frequencies.

Several factors determine thallium linewidths and second moments in polycrystalline solids. The most important factors are the CSA, direct through-space–dipolar interactions, indirect spin–spin interactions, coupling to quadrupolar nuclei,

and motional averaging. In some cases, the CSA will be significantly larger than the total line broadening from all other sources. In such cases, NMR spectra of powders or glasses are characteristic of powder patterns from which the value of the CSA and the values of the principal elements of the shielding tensor can be determined. If the line broadening from chemical shift anisotropy is smaller than that resulting from other factors, then broad, symmetrical NMR lines are observed. The magnitude of the CSA can still be determined in this case from the slope of a plot of the second moment as a function of the square of the applied magnetic field strength.

Direct dipole–dipole interaction might be expected to contribute significantly to thallium NMR linewidths since the magnetogyric ratios of ^{205}Tl and ^{203}Tl are large. If the structure of the sample is known, the contribution of the direct dipole–dipole interaction to the second moment can be determined using the method of Van Vleck.⁵⁷ For those cases in which structural details are unknown, the absence of an orientation-dependence of the linewidth of a single crystal suggests the absence of dipolar broadening. Dipolar broadening is independent of the magnetic field strength.

Line broadening, as the result of indirect spin–spin coupling, has been found to make a significant contribution to the total linewidth of thallium NMR lines. This type of interaction is independent of the magnetic field strength but depends upon the transmission of nuclear spin information indirectly through intervening electrons. The electrons couple with the nuclear spins via dipolar or hyperfine interactions, and correlation between the electrons then results in the indirect nuclear interactions. Two types of indirect interactions are possible. When only *s* electrons transmit nuclear spin information, the interaction is of the scalar exchange type. When *s* and *p* electrons are involved, the interaction becomes a tensor quantity and is of the pseudodipolar type. If both electrons are in *p* orbitals, both exchange and pseudodipolar interactions exist. In the single crystal rotation experiment, it is not possible to separate directly the orientation dependence of the second moment into dipolar and pseudodipolar contributions. However, since the total orientation dependence represents the sum of these, calculation of the dipolar second moment using the Van Vleck⁵⁷ approach allows the pseudodipolar contribution to be estimated. Scalar-exchange broadening is, of course, independent of orientation.

The effect of quadrupole coupling on the linewidth of spin- $\frac{1}{2}$ nuclei in the solid state has been investigated.⁵⁸ It has been shown that quadrupole broadening may add a factor of up to 1.84 times the dipolar contribution to the second moment. Quadrupolar interaction will have the same effect on both ^{205}Tl and ^{203}Tl .

Motional narrowing can occur in both the melt and the solid state. Chemical shift anisotropy is averaged by fast rotational reorientation, as are dipolar and pseudodipolar interactions. Exchange-broadened lines may also be narrowed at the onset of molecular motion. In this case, the narrowing results from the modulation of the distance between interacting nuclei rather than from angular motion. The abrupt narrowing of thallium NMR lines is usually taken as evidence of a phase transition in a solid.

The NMR properties of metals are determined predominantly by the interactions of nuclei with conduction electrons. The NMR shift of thallium in a metallic sample arises from the coupling with the magnetic moments which derive from

the spins of the conduction electrons themselves. This type of NMR shift found in metals is known as the Knight shift.⁵⁹ The Knight shift for thallium in a variety of metallic systems has been measured. The Knight shift can exhibit an anisotropy just as the chemical shift can.^{60–62} Spin–lattice relaxation in metals and alloys is usually the result of mutual spin flips between nuclear magnetic dipole moments and the magnetic moments of conduction electrons at the Fermi level. When these electrons are highly localized, the relaxation time is related to the Knight shift by the Korringa equation.⁶³ For the case where conduction electrons localize on a particular thallium site, the relaxation rate will increase proportionally above that predicted by the Korringa equation. Comparison of the experimentally determined relaxation time with that predicted by the Korringa equation provides a useful method of obtaining information about internal electronic structure in the metal or alloy.

A number of NMR investigations of the Knight shift and relaxation of thallium metal in the solid state and melt have been performed.^{3,9,61,64–70} NMR studies of thallium in a number of alloys and intermetallic compounds such as $\text{LiCd}_{1-x}\text{Tl}_x$, $\text{CaCd}_{1-x}\text{Tl}_x$ ($0 \leq x \leq 1$), La_3TlC , $\text{La}_3\text{Tl}_{0.5}\text{In}_{0.5}$, $\text{La}_3\text{Tl}_{0.8}\text{Pb}_{0.2}$, $\text{Tl}_{1-x}\text{Te}_x$, TlSe , Tl_2Se_3 , TlAsSe_2 , $\text{PSe}_{2.5}\text{Tl}$, PSe_4Tl , $\text{As}_2\text{Se}_3\text{--Tl}_2\text{Se}_3$, $(\text{Tl}_2\text{Se})_x\text{--}(\text{As}_2\text{Se}_3)_{1-x}$, $\text{In}_{0.5}\text{Tl}_{0.5}$, $\text{Tl}_{0.3}\text{WO}_3$, TlGaSe_2 , $\text{TlNb}_2\text{O}_5\text{F}$, $\text{Tl}_x\text{NbO}_{2+x}\text{F}_{1-x}$, $\text{Tl}_{3.5}\text{TaO}_{2.5}\text{F}_{0.5}$, TlPbI_3 , NaTl , and Na_2Tl , have been reported.^{71–105} A number of thallium NMR studies of the thallium barium calcium copper oxide superconductor have been made^{106–120} as well as that of the superconductor type, La_3Tl .⁷² The investigations with the superconductors involved the determination of the shift, spin–lattice relaxation time, lineshape, and vortex lattice formation.

The favorable NMR properties of thallium have permitted a number of investigations of thallium ions adsorbed on surfaces and contained in zeolites.^{121–127} The structures of thallium silicate, germanate, borate, and phosphate glasses of varying thallium content have been investigated using thallium chemical shifts and linewidths.^{128–136} The thallium CSA in TiPO_3 glass has been determined to be 560 ppm although the isotropic chemical shift is -50 ppm to low frequency. Thallium sites in TiPO_3 glasses are moderately ionic but not as ionic as that found in the polycrystalline form.

Thallium NMR spectroscopy has been used to study a number of paramagnetic compounds such as TlCoF_3 , TlMnF_3 , TlMnCl_3 , TlNiCl_3 , $\text{Tl}_3\text{Fe}(\text{CN})_6$, $\text{TlFe}(\text{SO}_4)_2$, and $\text{Tl}_3\text{Co}(\text{CN})_6$.^{24,137–139} Unpaired electron spin density on thallium in these compounds produce very large shifts to high frequency, as much as $+14\,000$ ppm for $\text{Tl}_3\text{Fe}(\text{CN})_6$. As might be expected, thallium linewidths are very large in these compounds, ranging from 2.5 to 74 kHz.

Solid state and melt thallium NMR studies of many of the common Tl(I) salts have been performed. A number of Tl(III) compounds and a few organothallium compounds have been investigated. In general, the effect of changes in temperature on the thallium chemical shift in solids and melts is often very pronounced. For example, the ^{205}Tl chemical shift in solid Tl(I) acetate varies by 5 ppm $^\circ\text{C}^{-1}$. It must be mentioned that for the large number of compounds studied, none exhibits a shift that has a negative temperature dependence. The positive dependence of the chemical shift upon temperature arises from the enhanced vibrational overlap of the thallium anion wavefunctions, resulting in additional paramagnetic shielding with increasing temperature. Because

of the extreme sensitivity of the thallium chemical shift to changes in chemical environment, a change in the chemical shift would be expected to occur at the temperature of a phase transition. In fact, a change in chemical shift of several hundred ppm can occur at the phase transition. If sufficient data are available, the shift discontinuity and temperature dependence of the chemical shift can be used to calculate the distance of closest approach of ions in melts.^{140,141} The magnitude of the chemical shift discontinuity may be used as a measure of the overall difference in the two phases, where large discontinuities are associated with the greatest dissimilarities. For this reason it appears that the thallium environments in melts of Tl(III) salts may be more like those in the solids. It seems likely that strong cation–anion interactions in these salts persist upon fusion and that the basic units in the melt may be relatively covalent. Thallium(I) carboxylates also exhibit little discontinuity at the melting point.^{140,142} The absence of linewidth discontinuity at the melting point also suggests great similarities between the structures of the solid and the melt in these compounds (i.e., the carboxylate anions bind tightly to the thallium cations in both the solid and the melt).

There are cases where thallium linewidths are very sensitive to phase changes. An excellent example of this is observed with TlNO_3 . The ^{205}Tl linewidth in this compound is essentially independent of temperature for a given phase, α , β , or γ . However, a sudden narrowing of the resonance line occurs at the transition from orthorhombic γ to hexagonal β and again at the transition from β to cubic α .^{136,143,144} The β to α transition is accompanied by a 100-fold increase in electrical conductivity and marks the onset of Tl(I) diffusion in the solid.¹⁴³ Further support for this was obtained from thallium relaxation time studies.^{145,146} Ions, by their very nature, exhibit only weak electronic interactions with their surroundings. Therefore, the degree of ionic character limits the magnitude of the CSA that can be observed for an ion. Comparatively small CSAs are anticipated for highly ionic systems, while the potential exists for much greater anisotropies if stronger ionic interactions are present. There is little doubt as to the highly ionic nature of ^{205}Tl in pure TlNO_3 since its resonance line lies some 135 ppm to low frequency of that of aqueous $^{205}\text{Tl}^+$. The covalency of this salt has been estimated to be only 0.6%.¹⁵ The chemical shift of -300 ppm indicates even greater ionic character for Tl(I) isolated in the KNO_3 . Yet, at high temperatures even this very ionic Tl(I) ion exhibits a rather remarkable CSA of 91 ppm. The isotropic chemical shift of ^{205}Tl in TlClO_4 is quite far to low frequency, suggesting that this is a very ionic salt. Nevertheless, polycrystalline TlClO_4 was found to present a classic powder pattern characteristic of axial symmetry with a CSA of 117 ppm.¹⁴⁷ Dilution of TlClO_4 in a KClO_4 matrix causes the anisotropy to increase to 149 ppm. That a salt with such high ionic character can still exhibit a CSA of that magnitude testifies to the extreme sensitivity of the thallium chemical shift to small electronic effects.

A number of thallium NMR studies have been made of the Tl(I) halides. In addition to the determination of the chemical shift of ^{205}Tl in TlF, it has been shown that the ^{205}Tl linewidth is due mainly to direct dipolar interactions between ^{205}Tl and ^{19}F .^{26,140,148–150} Thallium NMR studies of TlCl suggest that the thallium linewidth results mainly from scalar interactions between thallium nuclei. For TlBr the thallium NMR linewidth is significantly larger than that observed for TlCl . Indirect

spin exchange has been shown to be a very important source of line broadening for TlBr .^{148,149,151} Thallium(I) iodide exhibits a phase transition from orthorhombic to cubic form at about 160°C . Thallium NMR spectra of the two forms are significantly different. The ^{205}Tl resonance lines in both modifications are shifted well to high frequency of aqueous Tl(I), with the cubic form to higher frequency.¹⁵² The thallium linewidths of orthorhombic and cubic TlI are quite different. It has been suggested that Tl–Tl exchange interactions are important in cubic TlI but not in the orthorhombic form.^{152,153} Indirect Tl–I spin exchange has been suggested as a major source of line broadening in both forms of solid TlI, in addition to quadrupole broadening and CSA.¹⁵² Thallium-205 chemical shifts have been obtained for molten Tl_2Cl_4 ,^{37,154} and Tl_2Br_2 .³⁷ In both cases, two signals were observed which were attributed to equal amounts of TlX and TlX_3 . For the compound, Tl_2Cl_3 , two signals of relative intensity 3:1 were observed which were attributed to the presence of $\text{Tl}_3(\text{TlCl}_6)$.²⁶ Thallium-205 NMR studies of mixed-salt halides in the solid and melt state have been performed to explore the effect of covalency on the thallium chemical shift.^{37,155,156}

The effect of phase change on the NMR parameters of thallium in the carbonate,^{14,188} formate,^{26,157,158} acetate,^{158,159} cyanide,¹⁶⁰ and thiocyanate¹⁶¹ salts has been extensively studied.

A number of Tl(III) salts have been studied in the melt and solid state using ^{205}Tl NMR spectroscopy. The chemical shift of $\text{Tl}(\text{ClO}_4)_3$ has been determined as a function of temperature in the melt and the solid state.¹⁴⁰ This salt exhibits the only known negative change in chemical shift upon fusion, implying a decrease in covalency in the melt. Chemical shift and linewidth measurements have been made on $\text{Tl}(\text{ClO}_4)_3 \cdot 6\text{H}_2\text{O}$,¹⁴⁰ TlCl_3 ,^{140,162} and $\text{TlCl}_3 \cdot 4\text{H}_2\text{O}$ ⁵⁰ salts. Solids containing the TlX_4^- and TlX_5^{2-} moiety, such as $\text{Zn}(\text{TlCl}_4)_2$, KTlCl_4 , $\text{KTlBr}_4 \cdot 2\text{H}_2\text{O}$, $\text{Na}_2\text{TlCl}_5 \cdot 4\text{H}_2\text{O}$, $\text{Cs}_2\text{TlCl}_5 \cdot \text{H}_2\text{O}$, and $[\text{NBu}_4]\text{TlI}_4$ have been studied.⁵⁰ The $[\text{NBu}_4]\text{TlI}_4$ salt exhibits a remarkable chemical shift of -1560 ppm, which is about 1000 ppm to low frequency of the nearest Tl(I) salt. Compounds containing the TlX_6^{3-} and $\text{Tl}_2\text{X}_9^{3-}$ anions have also been studied, where X is a halogen atom.⁵⁰

4 BIOCHEMICAL APPLICATIONS

Alkali cations participate in a variety of biological processes. These include transmission of nerve impulses, initiation and maintenance of muscular activity, synthesis of proteins, regulation of metabolism, and activation and regulation of enzymes. Most knowledge concerning the biological chemistry of sodium and potassium has come from standard biochemical assays, electrochemical experiments, and the use of radioactive tracers. With the very high magnetic field NMR spectrometers currently available, NMR spectroscopy of the alkali cations in biological systems is quite feasible. However, there are cases for which the direct observation of some of these cations is not sufficient to solve the biochemical problem of interest because of the presence of very low concentrations or because the process of interest does not produce an adequate response in the observed NMR property. A number of probe ions with more favorable spectroscopic properties can be successfully substituted for investigative purposes.¹⁶³

A number of investigations indicate that thallium is a good surrogate for potassium and, to a lesser extent, sodium in biochemical systems.¹⁶³ The relative receptivities to the NMR experiment for ³⁹K(I) and ²⁰⁵Tl are 0.000473 and 0.1355, respectively. The sensitivity of the chemical shift to environmental changes of thallium is much greater than that of potassium or sodium. These facts suggest that ²⁰⁵Tl(I) is a good spectroscopic replacement probe for potassium and sodium in biochemical systems.

The structure of the binding site for the monovalent cation activator of *S*-adenosylmethionine synthetase from *Escherichia coli* has been characterized by ²⁰⁵Tl(I) NMR spectroscopy.¹⁶⁴ Thallium-205 NMR spectroscopy has been used to determine that the monovalent cation binding site in (Na/K)-ATPase is very near the divalent cation binding site.^{165,166} The effect of the presence of pyruvate kinase and its substrates on the chemical shift and relaxation of ²⁰⁵Tl(I) has been investigated^{167,168} as well as the interaction of Tl(I) with dipalmitoylphosphatidylcholine.¹⁶⁹ The interaction between the Tl(I) ion and antibiotic molecules, such as gramicidin, which acts as ion-transporting agents in membranes, has been studied with ²⁰⁵Tl NMR spectroscopy.^{170–175} The equilibrium binding constants of the group I and II cations with gramicidin A incorporated into model membranes have been determined with a combination of ²⁰⁵Tl NMR spectroscopy and competition binding.^{176–178} Thallium(III)-205 NMR spectroscopy has also been used to study the two binding sites for Fe(III) in transferrin.^{179,180}

1 BACKGROUND

The fundamental magnetic properties of tritium (^3H) were first reported in 1947^{1–3} in a series of NMR measurements which demonstrated the triton to be a spin- $\frac{1}{2}$ nucleus, with a positive magnetic moment about 6.66% larger than that of the proton. Despite the fact that these measurements established tritium as the most sensitive NMR-active nucleus, very little research was conducted over the next two decades. In short, we have found only 24 reports of tritium spectra in the first 30 years, and 14 of those were published in the period 1974–76. The lack of activity in the early years of tritium NMR development is readily rationalized—tritium is a radioactive nucleus and, with the limited sensitivity of early spectrometers, the quantities required to make the 1947 measurements were enormous. [No specific details of sample sizes were given, but 50 μL of HTO with 50% abundance of ^3H contains ca. 3000 GBq of radioactivity, and we estimate that the samples must have been of this order, i.e. 1850–18 500 GBq (50–500 Ci).] Hence, applications were limited to US National Laboratories, where facilities existed for obtaining and handling large quantities of tritium.

The first liquids ^3H NMR spectrum other than HTO was described in 1964,⁴ and set several important precedents for the newly developing field: (i) samples required large amounts of tritium (ca. 370 GBq in this instance); (ii) instrumental modification for ^3H detection was simple; (iii) proton–tritium couplings were obvious and readily measured; and (iv) the labeling pattern (or percentage of ^3H in various positions) was accessible from the spectrum. The sample used in this experiment was ethylbenzene prepared by metal-catalyzed reduction of phenylacetylene with tritium gas, and interestingly, the integrated ratio of methylene to methyl tritium was 1:1.5, not 1:1 as predicted. This result established high-resolution ^3H NMR as the tool of choice for analysis of tritiated products. The ‘nontextbook’ labeling pattern would have been difficult to detect and almost certainly overlooked using the conventional methods of the time, and incorrect assumptions about the labeling pattern would have affected downstream uses of the product. Indeed, biochemical applications of tritium have been slow to recover from the poorly characterized materials used in the 1950s and 1960s, when ^3H NMR was not available for product analysis.

Such demonstrations of the power of ^3H NMR spectroscopy led to a renewed interest in technical development in the late

1960s and early 1970s. Fortunately, the resurgence coincided with advances in instrumentation that allowed many other low abundance and/or low sensitivity nuclei to be routinely observed. This revolution in NMR spectrometer sensitivity was crucial. Since tritium sensitivity is > 75 -times that of ^{13}C , the ability to collect ^{13}C spectra at natural abundance clearly implies that tritium spectra could be obtained at the very low ^3H concentrations necessary to ensure the technique is safe and accessible to laboratories around the world. During this period, the sample requirement of 370–3700 GBq was drastically reduced to the range of 3.7–3700 MBq, depending on the complexity of the signals and the S/N level required. Of course, tritium detection by NMR still suffers from the inherent insensitivity of the technique, and some perspective can be gained from the fact that liquid scintillation counting (LSC) techniques can detect tritium at a level 10^{-7} lower than the highest field spectrometers of today. Yet, the detailed information which NMR yields about the chemical and magnetic environment of the nuclei makes this loss of sensitivity easy to justify.

The most influential force in the promotion of ^3H NMR spectroscopy as a routine research tool came from a fruitful collaboration between the University of Surrey and Amersham International. The early published work (1971–76) concentrated on methodology and proof of principle, and in the late 1970s a host of applications were reported. A number of other groups adopted the ^3H NMR approach, and by 1985 the Surrey group was able to publish an excellent compilation of techniques and results, describing a mature field.⁵ In this article, we will discuss the major features of ^3H NMR spectroscopy, and address the more recent, popular, and significant chemical applications.

2 SAFETY

Tritium is the very rare, but naturally occurring, radioactive isotope of hydrogen. It is a pure β -emitter and its 12.4 year half-life is convenient for most chemical or biological experiments. In Table 1 we list a variety of chemical and physical properties of tritium and elementary tritiated compounds.

As mentioned above, the large amounts of tritium necessary for early experiments made containment of tritiated NMR samples a point of major concern, and a number of convenient containment systems have evolved.⁵ Since tritium is a ‘soft’ β emitter, i.e. the energy of the β particle associated with its radioactive decay has very little penetrating power (Table 1, $E_{\text{max}} = 18.6 \text{ keV}$, $6 \mu\text{m}$ range in water), it is readily contained by a thin surface of plastic, Teflon, or glass. The major hazard is from ingestion, so care should be taken to keep samples sealed and clean on the exterior. We favor a double encapsulation approach using either a 3-mm glass tube inside a regular NMR tube, or a capped Teflon liner inside a sealed glass tube. These components are all commercially available.

Since the number of tritium nuclei needed for NMR detection exceeds that required for liquid scintillation counting by a factor of ca. 10^7 , the monitoring of equipment or personnel for contamination is readily accomplished by standard radiochemical techniques. At the minimum level readily detectable by liquid scintillation counting (LSC) (37 Bq L^{-1}) in a conventional urine analysis, the radiation exposure for an individual is less than 0.001 mSv y^{-1} . The sensitivity

Table 1 General Physical and Chemical Data for Tritium, and Common Radioactivity Units^a

Production	${}^6\text{Li}(n, \alpha){}^3\text{H}$
Radiation	β (100%); range = 4.5–6 mm in air, 6 μm in H_2O
β Energy	$E_{\text{max}} = 18.6 \text{ keV}$, $E_{\text{mean}} = 5.7 \text{ keV}$
Radioactive half-life	12.43 y (4540 d)
Biological half-life	ca. 10 d
Decay product	${}^3\text{He}$
Maximum specific activity	1064 GBq milliatom ⁻¹ (28.76 Ci milliatom ⁻¹)
Detection limit (in 24 h): LSC	0.037 Bq = 2.09×10^7 atoms (ca. 0.1 fmol)
NMR	1064 kBq = 6.02×10^{14} atoms (ca. 1 nmol)
Diameter of tritium atom (approx.)	1.1 Å
Volume of 37 GBq (1 Ci) of tritium gas at standard temperature and pressure	0.385 mL
Radiation produced by 37 MBq (1 mCi) in a man (70 kg = 40 L, i.e. 25 $\mu\text{Ci L}^{-1}$)	0.044 mSv d ⁻¹ (= 4.4 mrem d ⁻¹ , or 1.6 rem y ⁻¹)
Density, triple point, and boiling point of isotopic water molecules	H_2O : 1.000 g mL ⁻¹ ; 0.01°C; 100.00°C D_2O : 1.106 g mL ⁻¹ ; 3.82°C; 101.42°C T_2O : 1.214 g mL ⁻¹ ; 4.49°C; 101.51°C
Tritium content of pure T_2O at STP	117.4 TBq mL ⁻¹ (3173 Ci mL ⁻¹) 96.7 TBq g ⁻¹ (2614 Ci g ⁻¹)

^a37 gigabecquerels (GBq) = 1 curie (Ci) = 3.7×10^{10} disintegrations per second; 1 gray (Gy) = 10 000 erg g⁻¹ = 100 rad (units of absorbed dose); 1 sievert (Sv) = 100 rem (units of radiation exposure).

of LSC thus provides a level of detection well below the average exposure from background, medical, and terrestrial sources (3 mSv y⁻¹) or the current recommendation for a US Department of Energy radiation worker (<20 mSv y⁻¹). In addition, tritium uptake in the body is cleared as tritiated water (HTO) with a 10 day biological half-life, and this period can be drastically reduced by increasing fluid intake or by diuretics (e.g. water, beer, or coffee).

The hazards associated with analyzing ${}^3\text{H}$ samples are real, but have been grossly overemphasized in the past. A rational assessment of the risks involved is in order. Tritium is readily contained and is physiologically benign at the levels used in most high-resolution NMR experiments. When making a benefit/hazard judgement of conducting research on a 2220 MBq (60 mCi) sample contained as described above, it is reasonable to remember that safety lights in aircraft contain up to 370 GBq (10 Ci) of tritium, a marine compass may have as much as 28 GBq (0.75 Ci), and commonly available night sights for rifles contain 2 GBq (50 mCi) of tritium. The spectroscopist may be at greater risk from the lock solvent or other chemical entity in the sample than from the radioactivity, e.g. in a 0.25 mL sample containing 2220 MBq of a tritiated compound in C_6D_6 , there are 2 μmol of ${}^3\text{H}$ but 2.75 mmol of benzene. It is clearly less hazardous to handle a well-contained tritium sample than milligram quantities of neurotoxins and other biologically active compounds routinely analyzed in normal glass NMR tubes in many laboratories.

In summary, the handling and health physics of analyzing tritiated samples is an important but trivially solved consideration, allowing ${}^3\text{H}$ NMR spectroscopy to be readily executed in most laboratories having a pulsed Fourier transform NMR spectrometer.

3 FEATURES AND PARAMETERS

The characteristics of ${}^3\text{H}$ are compared with other common NMR active nuclei in Table 2. Tritium enjoys all the spectral advantages normally associated with spin- $\frac{1}{2}$ nuclei of high γ :

narrow lines, high sensitivity, and good dispersion. A brief perusal of Table 2 indicates the strong similarity between triton and proton magnetic properties, with tritium having slightly higher sensitivity and dispersion, and similar relaxation characteristics. The similarity between nuclei extends to chemical shifts, allowing one to use the extensive library of proton chemical shifts when making tritium resonance assignments. Since tritium also has extremely low natural abundance, spectra are free of background signals and this, combined with the a priori knowledge of chemical shifts from analogous protons, makes assignment of tritium spectra particularly straightforward.

Many of the favorable properties of tritium are illustrated in the spectra in Figure 1, where a comparison of proton, deuterium, and tritium NMR spectra of labeled glucose is shown. The superior resolution and dispersion of tritium over deuterium, a spin-1 nucleus, is obvious. Note that this labeled molecule is low molecular weight, and the line broadening of deuterium signals for larger molecules is even more striking, hence eliminating deuterium NMR as a useful technique for the structural analysis of large molecules in solution. In addition, since the dominant relaxation mechanism for deuterium is quadrupolar, NOE determinations are impossible, and sensitivity in saturation transfer is reduced due to rapid spin-lattice relaxation. In contrast, tritium analysis greatly simplifies the proton spectrum in Figure 1(a), particularly around the solvent where a less fortuitous proton chemical shift (or sample temperature) would have completely obscured one of the glucose signals under the HDO peak. Even in H_2O , tritium spectra require no solvent suppression and are much more easily assigned than the generally more crowded proton analog.

To understand the quantities involved in a tritium NMR experiment, one must be aware of the common units and conversion factors which are listed in Table 1. One of the most important benchmarks is that complete replacement of hydrogen by tritium in one position of a molecule gives a specific activity (SA) of 1064 GBq mmol⁻¹ (28.76 Ci mmol⁻¹). Obviously, for lower percentages of tritium replacement the SA value is proportionately reduced and this relationship,

Table 2 NMR Properties of ^3H and Common NMR Nuclei^a

Nucleus	Natural abundance	Spin	γ	Resonant frequency	Relative sensitivity ^b
^1H	99.984	$\frac{1}{2}$	26.7510	300.13	1.00

combined with a knowledge of the total number of millimoles of labeled substrate, readily yields the amount of radioactivity involved in the experiment.

3.1 Chemical Shifts and Referencing

Early measurements established that the ratios of nuclear screenings among the hydrogen isotopes was very close to unity. This implies that the chemical shift for a triton is essentially identical to that of a proton or deuteron in the analogous molecular environment. Thus tritium spectra can be referenced to, say, monotritiated TMS and chemical shifts will be nearly identical to proton chemical shifts. Since the tritium/proton Larmor frequency ratio is very well determined for TMS⁶ ($1.066\,639\,739 \pm 2 \times 10^{-9}$), in practice it is not necessary to add a tritiated reference material to a sample to achieve accurate referencing. Instead, a simple measurement of the *proton* frequency of a reference material and multiplication by the figure above gives the tritium resonance frequency for the reference. This procedure is known as ghost referencing. Some care must be taken in very precise work when using ghost referencing because more careful studies of the Larmor frequency ratio for a variety of tritium-labeled materials^{6,7} have shown that nuclear screenings are not identical, but vary slightly with carbon–hydrogen (tritium) bond hybridization. Thus, when referencing tritiated methyl groups a TMS ghost may be appropriate, but a tritiated phenyl position is more accurately referenced by a phenyl proton and a slightly different Larmor frequency ratio. These differences are usually so small that they do not interfere with routine analysis, and are not discerned in a wide display (0–6 ppm), such as that in Figure 1.

3.2 Coupling Constants and Isotope Effects

Coupling constants between tritium and other nuclei may be calculated from the analogous proton coupling constants. In

particular, $J(\text{T,T})$ and $J(\text{T,H})$ are given by the relationships in Table 2, i.e. tritium–proton spin–spin coupling constants may be calculated as ca. 6.664% larger than the analogous proton constant. There is a small isotope effect on the coupling constant,⁸ and measurements have been reported for tritium coupled to a number of other nuclei besides protons including carbon, tin, silicon, and boron.

Although there are isotope effects, measurement of a $J(\text{T,H})$ value is still an accurate way of predicting a proton–proton coupling constant, since the calculation involves division by 1.06664 rather than multiplication by 6.5144, as required by prediction from $J(\text{D,H})$. For isochronous protons (e.g. methyl protons having degenerate chemical shifts), measurement of the $J(\text{T,H})$ value readily yields a usually ‘invisible’ coupling constant (see Figure 2, below).

Besides the small isotope effects on nuclear screening and on coupling constants discussed above, there are also more commonly observed isotope effects on tritium chemical shifts caused by substitution of a heavy isotope in place of a proton. These are largest and therefore most easily observed when a geminal proton is replaced by a triton. This effect was first reported in analyses of highly tritiated methyl groups,⁹ where the R-CT_3 singlet was resolved from the $\text{R-CT}_2\text{H}$ doublet in the proton coupled tritium spectrum. The proton-decoupled spectrum was used to show that this primary isotope effect is ca. 0.025 ppm (i.e. 2.4 Hz at 96 MHz).

Figure 2 illustrates tritium isotope effects on chemical shifts and demonstrates how the methyl $J(\text{H,H})$ may be calculated from measured $J(\text{T,H})$ values, as discussed above. A sample of *m*-xylene was tritium-labeled by Raney nickel catalyzed exchange with T_2 , which is known to give almost exclusive methyl tritiation. All three tritio-methyl species are produced, as shown in the proton-decoupled tritium spectrum in Figure 2(a), where these species are separated by the primary isotope effect ($\Delta\delta$) on the tritium chemical shift. At 320 MHz, tritium signals from methyl groups have a proton–tritium coupling constant which is double $\Delta\delta$, so that the proton-coupled tritium spectrum in Figure 2(b) has a deceptively simple

Figure 1 Hydrogen NMR spectra of D-glucose in water. (a) Proton spectrum of C-1 tritiated D-glucose; the large peak is due to HDO. (b) Proton decoupled deuterium NMR spectrum of C-1 deuterated glucose; DMSO is an integration marker. (c) Proton-coupled tritium spectrum of C-1 tritiated glucose, labeled by the same catalytic technique as in (b)

appearance. The splitting patterns are shown on the figure, and our assignments are readily verified by integration of the signals in each of the spectra. The methyl $J(\text{H},\text{H})$ for *m*-xylene methyl groups may be calculated from the observed $J(\text{T},\text{H})$ value.

Secondary tritium isotope effects on chemical shifts have also been well quantified,¹⁰ and the primary deuterium isotope effect on tritium chemical shifts is also easily measured (Table 2).

3.3 Tritium NMR Intensity and the NOE

One of the major advantages of tritium NMR spectroscopy is that the labeling pattern in a sample may be determined without the time-consuming and laborious degradative determinations previously required.¹¹ Indeed, a tritium spectrum gives nondestructive, quantitative information on relative tritium abundance at different sites in a molecule. Of course, care must be exercised in any measurement of NMR peak intensities so that accumulation of the data does not *differentially* affect the various peaks. When proton decoupling is used, for example, the tritium intensities will be affected by the Nuclear Overhauser Effect (NOE). Because of the frequent

Figure 2 Deceptively simple tritium NMR spectra in C_6D_6 of *m*-xylene labeled by T_2 gas exchange over Raney nickel catalyst. (a) Proton-decoupled tritium spectrum showing peaks for $\text{R}-\text{CH}_2\text{T}$, $\text{R}-\text{CHT}_2$, and $\text{R}-\text{CT}_3$ species separated by $\Delta\delta = 0.025 \pm 0.001$ ppm (7.89 ± 0.21 Hz at 7.1 T). (b) Proton-coupled spectrum showing overlapped tritium multiplets separated by $J(\text{H},\text{T}) = 15.58 \pm 0.21$ Hz

use of proton decoupling in tritium experiments, the importance of this effect has been the subject of several studies and discussions.¹² While the maximum theoretical NOE enhancement to tritons from proton irradiation is 47%, the observed enhancements vary from 10–35%. More importantly, there are situations where differential NOEs may prejudice tritium spectral intensities, such as a labeled molecule with a high abundance of tritium in a position without neighboring protons and a second tritiated position which has many relaxation partners, and integrals should only be compared when these issues have been considered.

3.4 Relaxation

The similarity of tritium and proton nuclei means that their pathways for relaxation are nearly identical. A feature of tritium NMR is that the simple spectra allow straightforward relaxation measurements. The analogous measurements in proton spectra can be difficult due to spectral crowding, solvent suppression, or the complexity of the physical system. Hence tritium relaxation can be the more useful probe of molecular interactions. A classic example is the use of proton and tritium relaxation measurements combined with homo- and heteronuclear saturation transfer experiments to study the relaxation of water molecules in the presence of a macromolecular suspension.¹³ A rather simple suspension was created

by the formation of egg phosphatidylcholine/cholesterol lipid bilayers in solution. In a lipid suspension the water can exist in two distinct environments, a 'free' state exhibiting bulk water properties, and a motionally hindered or 'bound' state that is associated with the lipid in a hydration shell. Nuclei in these populations relax differently. The free water has the familiar characteristics of small rapidly tumbling molecules in solution, while the bound water has an additional slow component of tumbling due to its association with the lipid. This lipid-induced hydrodynamic effect causes a more rapid relaxation in the bound state and the presence of two water populations with different relaxation rates makes the overall relaxation behavior of the water signal complex. In general, it will depend on a combination of processes including the hydrodynamic effect, chemical exchange between free and bound environments, and the dipolar interaction (cross relaxation).

In the investigation of these processes, tritium doped water was used to separate the exchange contribution from other relaxation processes in the heteronuclear tritium-proton experiments. The measurements made on this rather complicated system were thus simplified to an analysis of several single-line spectra using inversion-recovery and saturation transfer experiments. The results indicated that the dipolar interaction (in the spin diffusion limit) dominates the relaxation of the water, and two models of this limit were proposed which accurately predicted the results, including a rigid and dynamic description of the lattice in the lipid solution. A complete model of the relaxation behavior of water is very desirable since the difference in relaxation properties of free and bound water populations is the basis for contrast and tissue characterization techniques in magnetic resonance imaging.

4 APPLICATIONS

We will limit the discussion here to chemical applications: (i) analysis of labeled materials for chemical and radiochemical purity; (ii) reaction mechanisms and tritium NMR techniques; (iii) specific activity measurements; (iv) solution conformation, stereochemistry, and optical purity; (v) proton exchange studies; and (vi) miscellaneous tritium NMR studies. Biological applications of ^3H NMR, e.g. ligand binding, metabolism studies, etc., are discussed elsewhere (see *Tritium NMR in Biology*).

4.1 Analysis of Labeled Materials

The vast majority of reports involving ^3H NMR spectroscopy describe the products of tritium-labeling reactions, and in this application the technique is invaluable. Tritium NMR has been used extensively for the investigation of many tritium exchange techniques, including radiation-induced and acid-, base-, metal-, or zeolite-catalyzed reactions.¹⁴ In general, these techniques rely on the replacement of a hydrogen atom by a tritium (i.e. exchange) in the native structure, and give low specific activity products which may contain tritium in one of several distinct sites.

In contrast, high level tritium labeling usually involves a synthetic transformation such as dehalogenation, hydrogenation, or hydride reduction of a suitable precursor. Dehalogenation reactions are an attractive method for introducing tritium

into a compound, but surprisingly these reactions rarely give quantitative replacement of halogen by tritium, even when 100% T_2 gas is used. Our experience is that 10–30% of product molecules will incorporate adventitious hydrogen (^1H) rather than ^3H . In general, the shorter the reaction time, the less hydrogen incorporated (i.e. the higher the SA value obtained), and it is advisable to use an iodo derivative as the substrate since the facility of halogen removal is $\text{I} > \text{Br} > \text{Cl} > \text{F}$. Also, 1 equiv. of organic base (e.g. triethylamine) enhances the reaction rate and neutralizes the acid formed.

The power of tritium NMR in the analysis of a tritiodehalogenation reaction product is best illustrated by an example. Figure 3(a)–(e) show a full proton and ^3H NMR analysis of a peptide labeled by catalytic dehalogenation of the analogous 3,5-diiodotyrosyl peptide. The aromatic portion of the proton spectrum of the tritiated material [Figure 3(a)] shows ca. 15% proton intensity at the tyrosine 3 & 5 chemical shift, with the usual tyrosine 2 & 6 and Phe aromatic signals. Note that the splitting of the tyrosine 2 & 6 doublet reflects $J(\text{T},\text{H})$, not coupling to the 3 & 5 protons. The proton-coupled tritium spectrum in Figure 3(b) shows a clean doublet at the tyrosine 3 & 5 chemical shift for the incorporated tritium. Broadband decoupling of the protons yields the singlet tritium signal in Figure 3(c), as expected. Selective irradiation at the tritium tyrosine 3 & 5 frequency causes the tyrosine 2 & 6 doublet to collapse, as shown in the proton spectrum in Figure 3(d) [cf. Figure 3(a)]. Similarly, selective ^1H decoupling at the tyrosine 2 & 6 frequency yields a singlet tritium signal at the tyrosine 3 & 5 chemical shift [Figure 3(e)]. These experiments are readily performed and characterize the product beyond any doubt.

The other most common method for introducing high levels of tritium is catalytic hydrogenation of an unsaturated site on a suitable precursor. Interestingly, heterogeneous metal-catalyzed hydrogenation reactions often do not yield 'textbook' results, and it is remarkable that so few researchers are aware of these details, despite their repeated demonstration.⁵ Two effects contribute to the complicated mixture of isotopomers obtained from these reactions:¹⁰ (i) there is an inventory of hydrogen ($^1\text{H}_1$) in the catalyst, solvent, substrate, and reaction vessel which serves to **decrease** the maximum level of tritium which may be incorporated into the labeled material; and (ii) vinylic and allylic protons may undergo metal-catalyzed exchange prior to saturation of the multiple bond, thus leading to **increased** specific activity.¹⁵ As a result, the products of a hydrogenation reaction often have (a) lower than theoretical incorporation of tritium, (b) tritium in positions remote from the original site of unsaturation, and (c) unequal amounts of tritium on each side of the original multiple bond.

When ^3H NMR is used to analyze the products of both heterogeneous and homogeneous catalysis of an identical reduction, the complexities of heterogeneous catalysis are clear. Such a comparison of tritiation techniques for the labeling of an unsaturated phospholipid molecule is shown in Figure 4. All the problems described above for heterogeneous catalysis complicate the spectrum shown in Figure 4(a), including small amounts of tritium incorporated at the positions adjacent to the double bond. In contrast, the product of the homogeneous tritiation using Wilkinson's catalyst [Figure 4(b)] shows clean addition of tritium, with a 1:1 ratio at the C-7 and C-8 positions. A ^3H – ^3H COSY analysis of this product [Figure 4(c)] showed that the two

Figure 3 Proton and tritium NMR spectra in D_2O of a peptide labeled by catalytic tritio-dehalogenation of the appropriate diiodotyrosyl peptide. (a) Aromatic region of the proton spectrum showing signals from the phenylalanine residue and a clean doublet from the tyrosine 2 and 6 protons. Residual proton signals are obvious from the tyrosine 3 and 5 position. (b) Tritium spectrum showing the doublet of the tyrosine 3 and 5 tritons coupled to the 2/6 protons. (c) Proton-decoupled tritium spectrum showing the tritium singlet from the 3 & 5 tritium atoms. (e) Selectively proton decoupled tritium spectrum, with irradiation only at the tyrosine 2 & 6 doublet

expected diastereotopic products were obtained, in a 1:1 ratio.¹⁶ Although this tritium analysis shows that Wilkinson's catalyst gives a very clean product, it is not applicable in all circumstances. Such mundane issues as sample solubility and recovery of the labeled material from the reaction mixture often affect the decision of which catalyst is used. Heterogeneous catalysts have the advantages that they are tolerant of a variety of solvent systems and are easily filtered away after the reaction. Wilkinson's catalyst is usually employed as a benzene solution and may not perform well in a binary mixture if the substrate is insoluble in benzene. In addition, Wilkinson's catalyst is designed to form an intimate mixture with the substrate, and postreaction separation steps need to be optimized for each new substrate.

4.2 Reaction Mechanisms and Tritium NMR Techniques

Tritium spectra are almost always simple, hence there has been no strong drive to apply more sophisticated NMR techniques to tritium analyses. However, the subtleties of exchange effects in heterogeneous catalysis and the complex products from enzymatic reactions often require careful interpretation, and such studies may be greatly enhanced by the use of modern multipulse approaches.

The following techniques have been applied to tritium analyses over the past decade: double quantum filtering, DEPT, 2D homonuclear COSY, 2D tritium/proton correlation, 2D J -resolved, and 2D NOESY and EXSY experiments. The NOESY and EXSY approaches have been used for macromolecular structure studies and are discussed elsewhere

Figure 4 Proton-decoupled tritium NMR spectra of a labeled phospholipid in D_2O . (a) Product of a heterogeneous catalytic hydrogenation reaction. (b) Product from catalytic hydrogenation in the presence of Wilkinson's catalyst. (c) $\{^1\text{H}\} {}^3\text{H}-{}^3\text{H}$ COSY of the product in (b)

Figure 5 Tritium NMR spectra of tritiated 3-indolepropionic acid in CD_3OD . (a) Proton-decoupled tritium spectrum of the product of a heterogeneous catalytic hydrogenation reaction using 15% T/H. (b) Double quantum filtered proton-decoupled tritium spectrum of the same product as shown in (a). The observed $J(\text{T},\text{T}) = 7.32 \pm 0.12 \text{ Hz}$, suggesting a $J(\text{H},\text{H})$ value of ca. 6.4 Hz

(see *Tritium NMR in Biology*). The pulse sequences we regard as most useful for analytical applications are the DQF and 2D J -resolved experiments. These have been used for detailed investigation of the 'nontextbook' results typically encountered in tritiation reactions, which are usually invisible in the corresponding reaction with ${}^1\text{H}_2$. Hence tritiation and tritium NMR spectroscopy provide an excellent approach for investigation of these imperfectly understood reaction mechanisms, as discussed below.

The research staff at Berkeley routinely use a mixture of 5–15% T_2 in H_2 for exploratory labeling reactions and in a training program. In the hydrogenation of 3-indoleacrylic acid using a 10% Pd/C catalyst and 15% T_2 in H_2 gas, simple statistics predict that 2.25% of labeled 3-indolepropionic acid product molecules will contain two ${}^3\text{H}$ atoms, 25.5% will have a tritium at one carbon or the other, and 72.25% will contain no tritium. The ${}^1\text{H}$ -decoupled tritium NMR spectrum in Figure 5(a) shows several features: (i) the large singlet signals arise from molecules containing one tritium atom, and it is obvious that unequal amounts of ${}^3\text{H}$ are incorporated across the double bond, and (ii) one signal from a small doublet can be discerned at the base of each singlet (asterisked), presumably arising from the doubly tritiated species. The unequal substitution pattern in the singly tritiated species is thought to arise from

exchange at those carbons prior to saturation of the double bond, and tritium NMR represents the best method for the further study of the mechanism of such exchange.¹⁵ The doubly tritiated species can be observed simply and directly by the application of a familiar multiple pulse technique, a double quantum filtered (DQF) experiment. The results of the DQF experiment on this molecule are remarkably clean, as shown in Figure 5(b). The spectrum is simple because the doubly tritiated species is the only one present with tritium homonuclear double quantum transitions, and is further simplified because all couplings to protons are heteronuclear and have been removed by broadband decoupling. This result has tremendous potential for the study of the mechanism of this type of addition and would not have been possible without the use of tritium NMR. Clearly this unique ability to separate labeled species and perform careful analysis of complex mixtures of isotopomers resulting from a theoretically simple tritiation reaction is essential for understanding the mechanism of these reactions.

Two-dimensional J -resolved ^3H NMR¹⁰ can be an even more powerful tool for the analysis of complex isotopic mixtures. β -Methylstyrene was tritiated by catalytic reduction with 100% T_2 over 5% Pd/C catalyst, to give highly tritiated n -propylbenzene with ca. 40% of the tritium on the α -methylene carbon, 50% on the β -methylene, and 10% in the methyl group. In addition, all of the multiplets for these tritiated positions showed a complex structure, not at all like the simple doublet of doublets which might have been proposed assuming clean addition of a tritium atom to each end of the double bond.

The methyl region of the proton-decoupled tritium J -resolved analysis of this sample (Figure 6) provided most

insight into the species giving rise to the various signals. There is a repeating and slightly overlapped singlet–doublet–triplet pattern, with each repetition moved successively to lower frequency by ^3H isotope effects. These first of these patterns (group A, Figure 6) is due to the species $\text{X}-\text{CH}_2-\text{CH}_2\text{T}$, singlet; $\text{X}-\text{CHT}-\text{CH}_2\text{T}$, doublet; and $\text{X}-\text{CT}_2-\text{CH}_2\text{T}$, triplet (species 1, 2, and 3), and the small change in chemical shift between these signals is the secondary tritium isotope effect induced by addition of a T at the β - CH_2 . There are similar patterns for the $-\text{CHT}_2$ (B) and $-\text{CT}_3$ (C) methyl species, successively moved to lower frequency by the primary tritium isotope effect on the methyl chemical shift. Inspection of several slices along the ω_2 dimension (submatrix, or .smx plots shown in Figure 6) show the relative abundance of each species in this mixture, and analysis of ω_1 slices allows us to extract all the $^3\text{H}-^3\text{H}$ coupling constants. Similar detailed analysis of the α - CH_2 and β - CH_2 regions of the J -resolved spectrum is also possible, and evidence was found for almost all of the 35 statistically possible, tritium-containing isotopomers. While the theoretical product, $\text{Ph}-\text{CHT}-\text{CHT}-\text{CH}_3$, was the most abundant species, the presence of another 34 tritiated isotopomers makes it clear that the mechanism of heterogeneous metal-catalyzed hydrogenation reactions is not as simple as commonly thought.

4.3 Specific Activity Measurements

The molar specific activity (i.e. radioactivity per unit weight) of tritium-labeled molecules is an important property, and tritium NMR may be used to determine this quantity.⁵ This approach is essential when the labeled material has no UV

Figure 6 The methyl section (0.68–0.93 ppm) of the contour plot of the proton-decoupled tritium J -resolved spectrum of n -propylbenzene, labeled by catalytic tritiation of β -methylstyrene. Sine-bell window functions were applied in both dimensions, $2k \times 512$ W transform, with magnitude calculation of peak intensities. The data were 'tilted' and 'symmetrized'

spectrum, or the high specific activity precludes weighing to determine sample concentration. An example of the latter was the determination of the SA value for a series of NaBT₄ preparations.¹⁷ Boron has two NMR active isotopes (¹⁰B, 20%, $I = 3$ and ¹¹B, 80%, $I = \frac{3}{2}$), so the proton spectrum of sodium borohydride in basic CD₃OD shows a large quartet (Na¹¹BH₄, $\delta = -0.168$ ppm, $J = 80.6$ Hz) and a small septet (Na¹⁰BH₄, $\delta = -0.166$ ppm, $J = 26.98$ Hz). The proton-decoupled tritium spectrum of exchange labeled NaBH(T)₄ shows a similar spectrum for each isotopomer, i.e. NaBH₃T, NaBH₂T₂, NaBHT₃, NaBT₄, shifted to lower frequency for each additional T. The multiplicity (redundancy) of the peaks is useful since peak overlap does not occur for all the species, and the isotopomer ratios may be compared between large quartet signals and the smaller septets. The amount of unlabeled (NaBH₄) material present was estimated by comparison with NaBH₃T signals in the proton spectrum. Knowing the mole ratio of all the isotopomers yields the SA value, and this property was compared for several production 'lots' of tritiated borohydride.

Even when determination of SA by UV spectroscopy and LSC counting, or by mass spectrometry, is possible, the NMR technique provides a useful cross check. In comparison to the sodium borohydride case above, a very simple example is given in Figure 7. Pinoline (6-methoxy-1,2,3,4-tetrahydro-9H-pyrido[3,4-*b*]indole) was labeled by catalytic hydrogenation of the unsaturated 3,4-dihydro analog. The product consisted of a mixture of three isotopomers containing zero, one, or two tritium atoms per molecule. Obviously, at the chemical shift of the C-1-methylene, one of these species has only a proton spectrum, one has a tritium spectrum, and one [R-CHT, $\delta = 4.39$ ppm, Figure 7(a) and (b)] has both a tritium and a proton NMR spectrum. In this case, the use of selective tritium [Figure 7(a)] or proton [Figure 7(b)] decoupling allows the observation of single lines for each of the isotopomers in the proton or tritium spectrum. Since the R-CHT signal occurs in both spectra, the molar ratio of the three species may be extracted from these spectra and the specific activity calculated.

4.4 Solution Conformation, Stereochemistry, and Optical Purity

Tritium NMR has been used to obtain the axial-equatorial conformational preference of tritium in [³H]cyclohexane.¹⁸ Tritium has the advantage of giving sharp and well-separated peaks that are well suited for high-accuracy integration at low temperatures, i.e. the peak separation in these experiments was ca. 150 Hz at 7.1 T, whereas the analogous deuterium experiment at 11.7 T gave a separation of only 36 Hz. [³H]Cyclohexane was made from cyclohexylmagnesium chloride in diethyl ether by the addition of HTO (5% tritium) followed by distillation of the tritiated product. A sample (ca. 0.9 GBq, 33 mCi) in CS₂ containing some CD₂Cl₂ for lock purposes was transferred into a standard thin-wall glass 5-mm NMR tube and ³H {¹H} NMR spectra were obtained at 320 MHz (300-MHz ¹H frequency). Narrow lines (ca. 2 Hz at halfheight) with good lineshapes were obtained at -88 °C by using the tritium FID as well as the ²H lock signal for shimming. For accurate integration it is essential that the base of the peaks be narrow and symmetrical, and that the baseline

Figure 7 Proton and tritium NMR spectra of tritiated pinoline in CD₃OD. (a) Selectively tritium-decoupled proton spectrum. (b) Selectively proton-decoupled tritium spectrum

is flat. A number of data sets, each consisting of the sum of 512 FIDs were acquired, several with the carrier at a higher frequency than the sample signals, some with the carrier at a lower frequency, and others with the carrier centered between the signals. The ¹³C satellites of both the axial and equatorial ³H signals ($\delta\nu = 0.471$ ppm) were visible in each set of spectra and gave $J(^{13}\text{C}, ^3\text{H}_{\text{ax}}) = 131.1$ Hz and $J(^{13}\text{C}, ^3\text{H}_{\text{eq}}) = 135.2$ Hz. Integration of the spectra showed that tritium prefers the equatorial over the axial site by about 46.9 J mol⁻¹ and a ³H EXSY experiment showed that the axial and equatorial tritium atoms are undergoing (slow) exchange at -88 °C. Conformational analysis by ³H NMR relaxation has also been used in enzyme ligand studies (see NT497-*Tritium NMR in Biology*).

The absolute stereochemistry of a tritium atom on a carbon may be determined by tritium NMR if there is another chiral center in the molecule. If this is not the case on the parent molecule, it can often be created by esterification or some other derivatization. This feature was exploited in analysis of tritiated ethanol produced by enzymatic oxidation of 'chiral ethane', i.e. CH₃-CHDT, as part of a study of the mechanism of methane monooxygenase.¹⁹ Tritium NMR analysis of the methylene region of the ethanol product showed signals from CH₃-CHT-OH and CH₃-CDT-OH, separated by the ²H isotope effect on the tritium chemical shift [Figure 8(a)]. Whereas this spectrum gives information on the relative rate of removal of an H or D atom in the oxidation process, it gives no stereochemical data. A simple derivatization with

Figure 8 Proton-decoupled tritium NMR spectra of the products from enzymatic oxidation of chiral ethane. (a) Ethanol in H_2O . (b) Derivatized ethanol in C_6D_6 , where $\text{R} = (2R)\text{-2-acetoxy-2-phenylethanoic acid}$

$(2R)\text{-2-acetoxy-2-phenylethanoic}$ (mandelic) acid yields ethyl mandelate, and the four possible species can be readily separated and quantitated by ^3H $\{^1\text{H}\}$ NMR, as shown in Figure 8(b). The *absolute* stereochemistry was previously established by a known synthesis of the deuterium-substituted molecules and proton NMR analysis.

Tritium NMR has been used to determine the optical purity of labeled materials. The use of a lanthanide shift reagent²⁰ or Pirkle's alcohol²¹ is a more general technique than the careful stereochemical determinations discussed above, and does not require the presence of an alcohol or amine functionality for derivatization to the appropriate ester or amide. This general approach is especially important for materials labeled at low tritium abundance because the optical properties of the bulk material may not be the same as the small subpopulation of labeled molecules.

4.5 Proton Exchange Studies

The NMR properties of tritium make it particularly well suited for in situ measurements of acid- and base-catalyzed proton exchange kinetics using tritium NMR spectroscopy.²² Despite the great sensitivity and simplicity of this approach,⁵ previous tritium NMR mechanistic studies of proton exchange have been confined to a static approach, i.e. the analysis of aliquots of a kinetic experiment.²³ In most circumstances, it is desirable to perform one-tube, accurate, kinetic experiments, especially for compounds which are only available in small amounts or have several exchanging positions with similar rates. Use of deuterium NMR spectroscopy, hampered by its low sensitivity and resolution, is inherently limited to initial

rates,²⁴ and if several positions are measured simultaneously, relative rates for the positions must lie within a small range. In contrast, tritium NMR spectroscopy allows one to measure the proton exchange kinetics of several compounds which may have similar rates or vary by a factor of 1000. Since tritium is a highly sensitive nucleus, the sample need not contain high levels of tritium for detection (especially compared with deuterium) and tritium therefore functions as a true tracer in the reaction kinetics. Only 20–180 MBq (0.5–5 mCi) per position ($1.5 \times 10^{-5}\%$ incorporation) is necessary for an adequate S/N ratio. This low tritium concentration also ensures the absence of tritium–tritium coupling, and the high γ and excellent relaxation characteristics of the nucleus lead to sharp resonance lines. The integrity of the reactant mixture may be monitored by proton NMR spectroscopy at any stage of the experiment. An inverse-gated proton-decoupling scheme may be used to ensure that single peaks are observed for each magnetic environment and that the relative peak integrals are not affected by NOE build-up. The quality of the kinetic data obtained by this technique suggests that it may be readily applied to other chemical proton-transfer systems.

As an example, this technique has been applied to the measurement of detritiation rates for the characterization of isotope effects. The Swain–Schaad relationship predicts that the deuterium and tritium isotope effects on the rate of a reaction are related as follows: $(k_{\text{H}}/k_{\text{D}})^x = k_{\text{H}}/k_{\text{T}}$. Theoretical calculations put x in the range 1.33–1.58, and a simple zero-point energy formulation of isotope effects gives $x = 1.44$. Deviations from this range have recently been used as evidence of tunneling in enzyme-catalyzed reactions, so the accuracy of experimental results in simple chemical systems is important. Such a simple system is the hydroxide ion-catalyzed enolization of acetone (a prototype ketone ionization reaction), but the originally published measurements give an anomalously low exponent, $x = 1.08$.²⁵ This exponent was based upon rates of detritiation of labeled acetone, which were determined by a technique that involved a difficult separation of acetone from water.

This reaction was reinvestigated²⁶ using tritium NMR to monitor the exchange of tritium between acetone and water in situ,²² thus avoiding the troublesome acetone–water separation. In NMR experiments using a range of base concentrations, the tritium signal from the acetone at $\delta = 2.1$ ppm was seen to decay while another resonance at $\delta = 4.7$ ppm, attributable to HTO, appeared (Figure 9). Least-squares fitting of the observed exponential rise and decay gave first-order rate constants that agreed well with each other.

When the NMR result was combined with k_{H} and a literature value of k_{D} determined by mass spectrometric measurements, it yielded $k_{\text{H}}/k_{\text{D}} = 7.2$ and $k_{\text{H}}/k_{\text{T}} = 19.2$. These isotope effects provide the Swain–Schaad exponent $x = 1.49 \pm 0.07$, which is in complete agreement with theory. Thus, tritium NMR provided a simple method for the measurement of an important exchange rate which was essentially inaccessible by chemical techniques.

4.6 Miscellaneous

Tritium NMR spectroscopy has been used in a number of other very specific chemical and physical investigations, most of which have been comprehensively reviewed elsewhere.⁵

Figure 9 A stacked plot of the proton-decoupled tritium NMR spectra of the base-catalyzed detritiation of acetone ($\delta = 2.1$ ppm) with exchange into the solvent (HTO, 4.7 ppm). The experimental parameters were: 500 μL , 0.04 M, NaOH; 5 μL , ^3H -acetone; $T = 298$ K; 120 transients; 100 experiments over 10.5 h (ca. 4-min interval for the first 50, then 8-min interval); spectrometer unlocked; $t = 0$ when the acetone was added, and the first spectrum was finished at $t = 20$ min. Seventy-seven spectra are plotted

These applications have included: (i) the observation of hydrogen-bonding effects on the chemical shift of proton versus tritium NMR signals; (ii) determination of solvent isotope effects and fractionation factors; (iii) aspects of radiation chemistry including sample radiolysis, studies of DNA hydration, and in situ production of labeled carbocations; (iv) investigations of labeled molecules in a liquid crystal environment; (v) solids tritium NMR and characterization of trapped gases in irradiated lithium hydride (tritide) samples;²⁷ and (vi) study of the origin of an anomalously large proton–proton coupling in transition metal polyhydrides.²⁸

5 CONCLUSION

We have discussed a wide range of applications where the use of tritium NMR has been useful, and some instances where it was essential. The similarity in NMR properties between protons and tritons means that many systems may be studied using either nucleus. Moreover, when proton systems become too complex, the spectral simplification of tritium spectroscopy suggests that tritium NMR should be considered. Radioactivity is the only issue hindering the universal application of tritium in many more general NMR studies.

1 INTRODUCTION

Measurements of ^{51}V NMR spectra of solids (see *Quadrupolar Nuclei in Glasses; Quadrupolar Nuclei in Solids*) with the use of modern NMR spectrometers (see *Spectrometers: A General Overview*) equipped with line-narrowing techniques for obtaining high-resolution spectra of solids (see *Double Rotation; High Speed MAS of Half-Integer Quadrupolar Nuclei in Solids; Magic Angle Spinning; Variable Angle Sample Spinning*) provide important information on the local environment of V nuclei.¹ The latter is known to be a key factor determining the activity and selectivity of heterogeneous catalysts. Due to this fact ^{51}V NMR solid state spectroscopy is successfully used for the studies of vanadia-based catalysts. The latter are used for the production of sulfuric acid, the selective oxidation of hydrocarbons, and also for reduction of atmospheric pollution.²

The results presented below show that ^{51}V NMR provides important information concerning the structure and reactivity of surface V sites. Herein will be discussed the main features of ^{51}V NMR in solids and its application for the studies of vanadium catalysts.

The vanadium-51 nucleus (natural abundance 99.76%) has a spin $I = \frac{7}{2}$, its electric quadrupole moment being $-4 \times 10^{-2} \times 10^{-24} \text{ cm}^2$; the relative intensity of ^{51}V NMR is 0.38 compared with an equal number of protons.

In general, three different types of interactions influence the ^{51}V NMR spectra of solid diamagnetic samples (see *Internal Spin Interactions and Rotations in Solids*): (1) the dipole interaction (see *Dipolar and Indirect Coupling Tensors in Solids*) of the magnetic moment of the ^{51}V nucleus with the magnetic moments of other nuclei that broadens the lines; (2) the quadrupole interaction (see *Quadrupolar Interactions*) of the ^{51}V nucleus with the electric field gradient that splits the lines and contributes to the shift of the central ($m_I = \frac{1}{2} \leftrightarrow m_I = -\frac{1}{2}$) line; and (3) the chemical shielding interaction (see *Chemical Shift Tensors*) that changes the position of the lines and makes them asymmetric.

In general, the lineshape might be rather complicated due to the simultaneous action of all types of interactions. For

powdered samples (the case typically met in heterogeneous catalysts) only the central transition ($m_I = \frac{1}{2} \leftrightarrow m_I = -\frac{1}{2}$) can most commonly be observed, while other transitions are too broad to be recorded. The line from the central transition is typically anisotropic, i.e. it has a rather complicated shape. This complicated shape reflects the fact that the observed line is actually a superposition of individual lines from vanadium sites having various orientations with respect to the external magnetic field. When these individual lines are narrow enough, the positions of the so-called discontinuity points can be readily identified in the overall ^{51}V NMR spectrum. From the position of the discontinuity points one can easily obtain the quadrupole coupling constant, χ , the asymmetry parameter, η , and the shielding anisotropy parameters σ_{11} , σ_{22} , and σ_{33} .³

Unfortunately, in the ^{51}V NMR spectra of many solid catalysts the effects from the discontinuity points are often completely or partially obscured due to the large broadening of individual lines. In this case computer analysis of the spectra recorded at various frequencies becomes necessary if one wishes to obtain the above-mentioned values. Note, that interactions affecting ^{51}V NMR spectra exhibit different frequency dependences. Indeed, the dipole interaction and the first-order quadrupole interaction do not depend on the spectrometer frequency ν_0 , while the second-order quadrupole effects are inversely proportional to ν_0 . The effects of the shielding anisotropy are directly proportional to ν_0 . Thus, at a sufficiently high ν_0 , the second-order quadrupole effects are suppressed and can be neglected, while the effects of the chemical shielding anisotropy become more pronounced and can be measured more precisely (*Chemical Shift Tensor Measurement in Solids*). A comparison of ^{51}V NMR spectra recorded at various ν_0 with computer simulated spectra has been demonstrated to allow sufficiently precise measurements of the spectral parameters characterizing vanadium sites in the solid catalysts.¹

Typical examples of computer simulated ^{51}V NMR spectra of V(V) sites in solid V_2O_5 are presented in Figure 1. Calculations were performed using the program for high magnetic fields ($B_0 > 7 \text{ T}$) when the perturbation theory approach can be applied, i.e. the values of the quadrupole and nuclear shielding terms are small when compared with the nuclear Zeeman energy.^{1,4}

Figure 1(a) and (b) show the influence of the first-order quadrupole effects on the calculated spectra of solid V_2O_5 at $\nu_0 = 105.15 \text{ MHz}$. Figure 1(c) demonstrates the spectral broadening in powdered or polycrystalline samples due to the distribution of quadrupole coupling constant.

2 VANADIUM-51 NMR SPECTRA OF SOLIDS WITH A WELL-CHARACTERIZED STRUCTURE. INTERRELATION BETWEEN ^{51}V NMR PARAMETERS AND THE LOCAL ENVIRONMENT OF V NUCLEI

To analyze the spectra of real catalytic systems one needs information on the spectra of vanadium compounds that might be present in the catalysts, as well as data on the interrelation between ^{51}V NMR parameters and the characteristics of the local environment of the V nuclei.

Figure 1 Computer simulated ^{51}V NMR spectra demonstrating the influence of the first-order quadrupole effects and line broadening on the spectra of solid V_2O_5 (at the frequency 105.15 MHz). The following parameters were used: $\chi = 0.805$ MHz, $\eta = 0.04$; $\sigma_{11} = 310$, $\sigma_{22} = 1280$, $\sigma_{33} = 270$ ppm. (a): The lineshape for the central transition ($\frac{1}{2}, -\frac{1}{2}$). (b) (Dotted lines): the lineshapes for all possible transitions: 1 ($-\frac{5}{2}, -\frac{7}{2}$), 2 ($-\frac{3}{2}, -\frac{5}{2}$), 3 ($-\frac{1}{2}, -\frac{3}{2}$), 4 ($\frac{1}{2}, -\frac{1}{2}$), the central transition, 5 ($\frac{3}{2}, \frac{1}{2}$), 6 ($\frac{5}{2}, \frac{3}{2}$), 7 ($\frac{7}{2}, \frac{5}{2}$). (b) (Solid line): the overall spectrum from all transitions. (c): Spectrum demonstrating the broadening of the lines from all transitions [dotted lines, numbered exactly as in (b)] and the overall spectrum from all transitions (solid line) due to the Gaussian distribution of quadrupole coupling constant χ . Dipolar linewidth $DF = 1.5$ kHz

The ^{51}V NMR spectra of various solid vanadium compounds^{1,3, 5–8} with well-characterized structures⁹ and of the vanadates of alkali metals, which are often used for the preparation of catalysts, have been studied.

In Table 1 the ^{51}V NMR chemical shielding parameters^{1,3,5,7,8} for vanadates are listed.

The ^{51}V NMR parameters of the large number of V compounds with a well-characterized crystal structure presented

in Table 1 prove the high sensitivity of NMR spectra toward details of the local environment of V nuclei.

In most cases the shape of ^{51}V NMR spectra measured in high magnetic fields ($B_0 > 7$ T) depends on the anisotropy of the chemical shielding tensor. The influence of the second-order quadrupole effects is typically smaller and often is quite negligible.¹⁰

The following conclusions on V coordination (tetrahedral or octahedral, regular or distorted) and the extent of association of vanadium–oxygen polyhedra can be drawn based on the type and magnitude of the chemical shielding anisotropy.^{1,7,10}

- For vanadium in regular tetrahedral sites (sites of the Q^0 type), the isotropic spectra with close values of the chemical shielding tensor components ($\sigma_{11} \approx \sigma_{22} \approx \sigma_{33}$) typically have $\Delta\sigma < 100$ ppm.
- For vanadium in slightly distorted tetrahedral sites with adjacent VO_4 tetrahedra sharing one common oxygen atom (sites of the Q^1 type), a fully anisotropic shielding tensor ($\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$) is typical, but with a larger $\Delta\sigma$ value ($\Delta\sigma = 70\text{--}300$ ppm).
- For vanadium in strongly distorted tetrahedral sites with adjacent VO_4 tetrahedra sharing two common oxygen atoms (sites of the Q^2 type), a fully anisotropic shielding tensor ($\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$) is typical with $\Delta\sigma = 300\text{--}375$ ppm.
- For vanadium in distorted octahedral sites (i.e. in a distorted octahedral environment of oxygen atoms), a nearly axial shielding anisotropy is typical with $\sigma_{11} \approx \sigma_{22} < \sigma_{33}$ ($\Delta\sigma = 450\text{--}900$ ppm for structures 4 in Figure 2 and $\Delta\sigma = 900\text{--}1300$ ppm for structures 5 in Figure 2).

Conclusions (a) to (d) are illustrated in Figure 2 for a family of Ti vanadates and V_2O_5 .

Note, that ^{51}V NMR spectra with approximate axial symmetry of the σ tensor should also be expected for VO_4 tetrahedra with symmetry close to C_{3v} , i.e. when one V–O bond differs significantly from the other three (which have about the same length) (sites of the Q^1 type). In this case the direction of $\sigma_{\parallel}$ will coincide with the direction of the V–O bond which differs from the three others, with $|\sigma_{\perp}| < |\sigma_{\parallel}|$ if this bond is shorter than the three others and $|\sigma_{\perp}| > |\sigma_{\parallel}|$ if this bond is the longest one.

A comparison of the shielding anisotropy $\Delta\sigma = |\sigma_{33} - \frac{1}{2}(\sigma_{11} + \sigma_{22})|$ for metavanadates whose structural data are known shows a good correlation between $\Delta\sigma$, on the one hand, and the angle $\text{O}_3\text{--V--O}_3'$ on the other hand [Figure 3(a)]. According to the structures of the metavanadates schematically presented in Figure 3(a) this angle characterizes the distortion of the tetrahedral environment of V. The larger the deviation of angle $\text{O}_3\text{--V--O}_3'$ from that in the regular tetrahedron ($109^\circ 28'$), the larger is $\Delta\sigma$.

Distortion of the VO_4 tetrahedra also results in an increase in the electric field gradient on the V nucleus. It seems natural to expect a correlation between $\Delta\sigma$ and the quadrupole interaction parameters, χ and η . Indeed, such a correlation has been found for metavanadates [Figure 3(b)].

In contrast to ^{27}Al ¹¹ and ^{29}Si ¹² (see *Aluminum-27 NMR of Solutions; Molecular Sieves: Crystalline Systems; Silicon-29 NMR*), the isotropic chemical shifts σ_{iso} for ^{51}V nuclei in vanadates are not too sensitive to V coordination (octahedral or tetrahedral). Compounds with rather different coordination may have very close σ_{iso} values. Thus, for vanadates, the anisotropy of the ^{51}V chemical shift is much more sensitive

to the character of the local arrangement of oxygen atoms around V than the isotropic chemical shift σ_{iso} . At the same time, for compounds with the same type of first coordination sphere, σ_{iso} depends notably on the type of atoms in the second coordination sphere of V, as also found for ²⁷Al and ²⁹Si atoms.^{11,12}

3 STUDY OF VANADIUM CATALYSTS

Typically, other techniques and approaches are used for identification of individual surface V species, in addition to ⁵¹V NMR. These include studies with magic angle spinning (MAS), NMR of nuclei of elements other than V and other spectroscopic methods, as well as chemical approaches. A combination of spectroscopic data with the measurements of catalytic activity allows one to identify the catalytically active sites.

3.1 V₂O₅/SiO₂ Catalysts

3.1.1 Prepared by Impregnation

Spectra of V₂O₅/SiO₂ samples prepared via impregnation of SiO₂ with NH₄VO₃ solution are presented in Figure 4. The

spectrum of the sample dried at 120 °C indicates only a slight change in the vanadium surroundings in comparison to that in NH₄VO₃ (spectrum 1a) and can be ascribed to (VO₄) species adsorbed on the SiO₂ surface. Calcination in vacuum provides a species that may differ both in the number of bonds with the surface and with neighboring vanadium species (spectra 2, 3, and 4 in Figure 4). Thus, lines present in spectra 2, 3, and 4 (calcination at 200 °C, 500 °C, and 700 °C) may be assigned to V species bonded to the surface via one, two, or three V–O bonds, respectively, as well as to V species bonded to neighboring vanadium species via one or two bonds.

Spectra of samples with high V concentrations (spectra 5 and 6) suggest the formation of the amorphous (nonregular) precursor of V₂O₅, since no sidebands are observed in the MAS spectra of these samples. Increasing the treatment temperature up to 700 °C results in the appearance of a line with highly resolved sidebands, due to rearrangement of the amorphous V₂O₅ structure to the crystalline one.

3.1.2 Prepared by VOCl₃ Interaction With SiO₂

The spectrum of the sample after VOCl₃ deposition suggests the presence of physically adsorbed VOCl₃ (narrow line with $\delta = -6$ ppm) and of VOCl_{3–n}(OSi)_n species bonded with the SiO₂ surface [a line with an axial anisotropy, Figure 4(b),

Figure 2 Relationship between the type of V coordination (tetrahedral or octahedral), the extent of polyhedra association (Q), and the shielding anisotropy $\Delta\sigma$. [As an example, the ^{51}V NMR spectra of Tl vanadates and V_2O_5 are presented: 1, Tl_3VO_4 (regular tetrahedra, Q^0); 2, $\text{Tl}_4\text{V}_2\text{O}_7$ (slightly distorted tetrahedra, Q^1); 3, TlVO_3 (strongly distorted tetrahedra, Q^2); 4, $\text{Tl}_2\text{V}_6\text{O}_{16}$ (distorted octahedra); 5, V_2O_5 (strongly distorted octahedron or square-pyramid)]

Figure 3 (a) Schematic representation of the structure of metavanadates of Na, Tl, Cs, Rb, and K and the dependence of the shielding anisotropy ($\Delta\sigma$) of their ^{51}V NMR spectra upon the $\text{O}_3\text{-V-O}_3'$ angle. This angle characterizes the distortion of the VO_4 tetrahedron from the regular form where $\text{O}_3\text{-V-O}_3' = 109^\circ 28'$. (b) Correlation between the shielding anisotropy $\Delta\sigma$ (data of Table 1) and the quadrupole coupling parameters χ and η (the latter taken from Pletnev et al.³ and Eckert and Wachs⁷) for metavanadates

Figure 4 (a) ^{51}V NMR spectra of $\text{V}_2\text{O}_5/\text{SiO}_2$ samples prepared via impregnation of SiO_2 with NH_4VO_3 (pH 7, 2.6 wt.% V_2O_5) 1, after treatment in vacuum at 120°C ; 2, at 200°C ; 3, at 500°C ; 4, at 700°C . Spectra 5 and 6 correspond to samples with a V content of 5.5 and 6.4 wt.% V_2O_5 , respectively, calcined at 500°C . (b) ^{51}V NMR spectra of $\text{VOCl}_3/\text{SiO}_2$ samples prepared by interaction of VOCl_3 from the gas phase with SiO_2 : 1, after VOCl_3 deposition; 1a, MAS spectrum of the same sample [line at 6 ppm corresponds to physically adsorbed VOCl_3 , anisotropic line with $\sigma_{\text{iso}} = 290$ ppm corresponds to $\text{VOCl}_2(\text{OSi})$ surface species]; 2, 3, 4, and 5, increase of H_2O content (replacement of Cl atoms to OH groups takes place during the first stage of hydration, then interaction of V species with the next H_2O molecules occurs); 6, spectrum 5 after evacuation at 100°C . All the spectra here and in the remaining figures were recorded at 105.15 MHz, pulse duration = $0.5\ \mu\text{s}$, pulse repetition frequency = 1 Hz. Chemical shifts are presented with respect to VOCl_3 as external reference

spectrum 1]. Deposition of VOCl_3 at room temperature yields complexes with $n = 1$ (a line with $\sigma_{\text{iso}} = 290$ ppm, spectrum 1a). Increasing the deposition temperature to 400°C leads to complexes with $n = 2$ or 3 . The first additions of water cause the disappearance of physically adsorbed VOCl_3 [Figure 4(b), spectrum 2], then water interacts with the $\text{VOCl}_{3-n}(\text{OSi})_n$ surface species producing partially hydrated $\text{VO}(\text{OH})_y\text{-Cl}_{3-n-y}(\text{OSi})_n$ ($y \leq n$, $n = 1, 2$, or 3) species (spectra 2 and 3) and fully hydrated $\text{VO}(\text{OH})_{3-n} \cdot 2\text{H}_2\text{O}(\text{OSi})_n$ species (for these species the sign of the anisotropy is opposite to that for species containing Cl in their coordination sphere, $\sigma_{\parallel} > \sigma_{\perp}$). Dehydration under mild conditions (100°C) results in the removal of water from the first coordination sphere and in the formation of associated tetrahedral complexes (spectrum 5). The latter was ascribed to $\text{VO}(\text{OSi})_3$ by Das et al.¹³

Application of magic angle spinning does not improve the resolution, unlike the situation when complexes contain Cl in the first coordination sphere. This indicates a nonregularity in the structure of the surface oxide complexes.

These data along with results presented by Lapina et al.¹⁴ show that after calcination at $400\text{--}500^\circ\text{C}$ similar complexes are formed on the SiO_2 surface by the different deposition procedures.

3.2 $\text{V}_2\text{O}_5/\text{Al}_2\text{O}_3$ Catalysts

Vanadium-51 NMR spectra of $\text{V}_2\text{O}_5/\text{Al}_2\text{O}_3$ catalysts prepared by interaction of Al_2O_3 with VOCl_3 , impregnation of Al_2O_3 with NH_4VO_3 , and ultra-high-intensity grinding (UHIG) of $\text{V}_2\text{O}_5\text{-Al}_2\text{O}_3$ mixtures are shown in Figures 5 and 6.

3.2.1 Prepared by Impregnation

The various ^{51}V NMR spectra of these catalysts can be classified in terms of the five different types of lines contained^{15,16} (Figure 5). Line A [spectrum (a)-1] observed for wet samples of low V content (1 wt.%) has been attributed to tetrahedral VO_4 species relatively loosely bound to the Al_2O_3 surface via one or two oxygen atoms. Line B, which was detected for calcined samples of low V content (1 wt.%) [spectrum (a)-2] was attributed to VO_4 tetrahedra bound more firmly to the Al_2O_3 surface via two or more oxygen atoms. Line C observed for samples with a large V content either dried or calcined [spectrum (a)-3] has been attributed to polynuclear V species of the decavanadate type on the Al_2O_3 surface. Line D is attributed to the AlVO_4 phase. It has been detected in calcined samples with a large V concentration [spectrum (a)-4]. From the MAS spectra, the σ_{iso} values for each of the three nonequivalent V sites in the structure of this compound were as follows: $\sigma_{\text{iso}1} = 668 \pm 5$; $\sigma_{\text{iso}2} = 747 \pm 5$; $\sigma_{\text{iso}3} = 780 \pm 5$ ppm. Line E ($\sigma_{\perp} = 310$ ppm, $\sigma_{\parallel} = 1270$ ppm) relates to V_2O_5 [spectrum (a)-5]. In the spectra of real catalysts, superposition of lines from different V sites occurs as shown in Figure 5(b).

3.2.2 Prepared by Interaction of Al_2O_3 With VOCl_3

Figure 6(a) shows that at least four types of particles are formed on the Al_2O_3 surface after VOCl_3 deposition: physically adsorbed VOCl_3 (narrow line with $\delta \approx 0$ ppm) and particles containing Cl atoms in the first coordination sphere,

i.e. $\text{VOCl}_{3-n}(\text{OAl})_n$, where $n = 1, 2$, or 3 (broad lines in the range from 0 to -1000 ppm, spectrum 1). The process of hydration occurs initially by hydration of the physically adsorbed VOCl_3 (disappearance of the signal at $\delta \approx 0$ ppm) and then exchange of Cl atoms in the first coordination sphere of V by OH groups takes place; after sample treatment at 500°C , the formation of V sites typical for catalysts prepared by impregnation are also formed [cf. Figure 6(a), spectrum 5 and Figure 6(b), spectrum 3].

3.2.3 Prepared by UHIG Treatment

The ultra-high-intensity grinding (UHIG) of $\text{V}_2\text{O}_5\text{-Al}_2\text{O}_3$ mixtures was found to induce a heterogeneous chemical reaction between these oxides producing highly dispersed V species on the support surface.¹⁷ The ^{51}V NMR spectrum of V_2O_5 after UHIG treatment demonstrates the broadening of the peaks from first-order quadrupole effects due to distortion of the local vanadium environment while the general crystal structure of V_2O_5 is retained [spectra 1 and 2 in Figure 6(c)]. Only a small part of the V_2O_5 reacts with Al_2O_3 when a $\text{V}_2\text{O}_5\text{-Al}_2\text{O}_3$ mixture is calcined for 14 h at 500°C (peak at -570 ppm) (spectrum 3). A more complete interaction between V_2O_5 and Al_2O_3 takes place in the samples after UHIG treatment at room temperature (spectrum 4). As the concentration of V increases, the other tetrahedral V state (peak near -750 ppm) appears. Subsequent calcination at 500°C produces V in octahedral coordination. In general, ^{51}V NMR spectra of the samples treated at 500°C after UHIG treatment show the formation of surface structures that are similar to those for $\text{V}_2\text{O}_5/\text{Al}_2\text{O}_3$ catalysts prepared by the conventional impregnation/calcination method.

Thus, the types of surface V species on Al_2O_3 are the same for all three preparation procedures discussed above. Their relative amounts depend in a similar way on the total V concentration on the Al_2O_3 surface and on the treatment temperature. At low V concentration species A prevail, while at the increased V concentration species B and C appear on the catalyst surface. At still larger amounts of supported V (>10 wt.%), V_2O_5 and AlVO_4 also form.

3.3 $\text{V}_2\text{O}_5/\text{MgO}$ Catalysts

Vanadium-51 NMR spectra of $\text{V}_2\text{O}_5/\text{MgO}$ catalysts, recorded at various vanadium content, show four different V sites on the MgO surface (Figure 7).¹⁸ Only one of them can be attributed to magnesium vanadate, $\text{Mg}_3(\text{VO}_4)_2$. Other V sites have been identified on the basis of correlations between the structure of the local environment of the V nuclei and the shielding anisotropy.

The narrow isotropic line with $\sigma_{\text{iso}} = 480$ ppm observed at low vanadium concentration (from 1.6–2.6 wt.% V) [spectra 1 and 2 in Figure 7(a)] has been attributed to isolated surface V atoms which have a virtually regular tetrahedral oxygen environment. Two broadened lines, i.e. an almost isotropic line with $\sigma_{\text{iso}} = 570$ ppm and a line with $\sigma_{\perp} = 510$ ppm, $\sigma_{\parallel} = 720$ ppm have been assigned to surface clusters with V atoms in a tetrahedral environment (spectra 2, 3, and 4). At large V content, orthovanadate $\text{Mg}_3(\text{VO}_4)_2$ ($\sigma_{\text{iso}} = 560$ ppm) is formed in the catalysts (spectrum 4). The calculated shapes of the individual lines for various V sites in $\text{V}_2\text{O}_5/\text{MgO}$ catalysts and

Figure 5 Classification of ^{51}V NMR lines observed in $\text{V}_2\text{O}_5/\text{Al}_2\text{O}_3$ catalysts prepared by Al_2O_3 impregnation with NH_4VO_3 solution. (a) Individual lines: 1, line A, $\sigma_{\text{iso}} = 520\text{--}590$ ppm, observed in wet samples at a V content from 1–2 wt.%; 2, line B, $\sigma_{\text{iso}} = 750$ ppm observed at a V content of 1 wt.% for samples calcined at 500°C ; 3, line C, $\sigma_{\perp} = 350$ ppm observed for wet samples at high V content; 4, line D from polycrystalline AlVO_4 ; 5, line E from polycrystalline V_2O_5 . (b) Spectra of various catalysts: 1, prepared by impregnation with NH_4VO_3 (pH 12, 2.2 wt.% V) dried at 110°C , superposition of lines A and B; 2, the same sample calcined at 550°C , superposition of lines A, B, and C; 3a, MAS spectrum of sample 3; 3, catalyst prepared via impregnation with VOCl_2 (pH 0.4, 14 wt.% V) calcined at 500°C , superposition of lines B, C, and D (line D gives well-resolved sidebands with MAS); 4, catalyst prepared via impregnation with NH_4VO_3 (pH 7, 14.8 wt.% V), the superposition of lines A, D, and E

Figure 6 Vanadium-51 NMR spectra of V_2O_5/Al_2O_3 catalysts at different stages in their preparation: (a) Catalysts prepared by interaction with gaseous $VOCl_3$: 1, spectrum after $VOCl_3$ deposition; 2, 3, and 4, increase of H_2O content; 5, sample 4 after calcination at $500^\circ C$. (b) Catalysts prepared by impregnation with NH_4VO_3 (pH 12, 3.8 wt.% V): 1, wet sample; 2, sample dried at $120^\circ C$; 3, sample calcined at $500^\circ C$. (c) Catalysts prepared by ultra-high-intensity grinding (UHIG): 1, V_2O_5 ; 2, V_2O_5 after UHIG; 3, $V_2O_5-Al_2O_3$ mixture (5 wt.% V_2O_5) calcined at $500^\circ C$ for 14 h; 4, after UHIG treatment at room temperature; 5, UHIG with subsequent calcination of the samples at $500^\circ C$ for 2 h

deconvolution of the experimental spectrum into individual lines are also shown in Figure 7(b) and (c). Figure 7(c) also presents the relative amounts of the various V species as measured by deconvolution of the experimental spectra.

Hence, the ^{51}V NMR spectra of V_2O_5/MgO catalysts allow one to form certain conclusions on the structure of surface V species and their concentration as a function of the total vanadium content.

3.4 V_2O_5/TiO_2 Catalysts

The influence of the admixtures on the structure of the supported species has been demonstrated for V_2O_5/TiO_2 supported catalysts^{1,19} (Figure 8). Spectra of catalysts prepared via the gas-phase reaction of $VOCl_3$ with TiO_2 followed by subsequent hydration and H_2O removal at $350^\circ C$ are shown in Figure 8(a). The catalyst prepared from the most pure anatase (impurities less than 0.1 wt.%) contains two tetrahedral (peaks at $\delta = -440$ and -560 ppm) and one octahedral species (peak at $\delta = -320$ ppm) as follows from spectrum 1 in Figure 8(a). An admixture containing sulfate anions (3.9 wt.%) increases the content of the octahedral vanadium species (spectrum 2). The presence of 3 wt.% Si leads to tetrahedral

vanadium complexes typical for V_2O_5/SiO_2 samples (peak at $\delta = -490$ ppm, spectrum 3) and with anatase containing Na (2.3 wt.%) the formation of Na_3VO_4 was observed (line with $\delta = -535$ ppm, spectrum 4). Similar surface species have also been identified for the same catalysts prepared by impregnation of the same anatase samples with a solution of vanadyl oxalate [cf. Figure 8(a) and (b)].

Thus, the type of surface V species on TiO_2 depends mainly on the presence of the impurities in anatase with the preparation procedure having a considerably smaller effect on the type of V sites on the catalyst surface.

Data analysis presented above and by Lapina et al.¹ shows that the structure of surface V species depends mainly on the type of support. The preparation procedure (impregnation, grafting, UHIG treatment) appears to have much less of an effect on the type of V sites on the catalyst surface provided that the concentration of vanadium and the treatment temperatures are the same.

At a V concentration less than 0.5 monolayer, surface tetrahedral species with different extents of distortion of the oxygen environment are formed, with the distortion depending on the type of the support used.

(a) For MgO and $AlPO_4$, the surface vanadium species has an almost regular tetrahedral environment with σ_{iso} depending

Figure 7 (a) ^{51}V NMR spectra of $\text{V}_2\text{O}_5/\text{MgO}$ catalysts of various vanadium content: 1, 1.6 wt.%; 2, 2.6 wt.%; 3, 5.0 wt.%; 4, 9.6 wt.%. The upper spectra were recorded without MAS; the MAS spectra are shown below. The isotropic chemical shifts are indicated by asterisks (*). (b) The simulated lineshapes of ^{51}V NMR spectra for various V species found in $\text{V}_2\text{O}_5/\text{MgO}$ catalysts: 1, isolated tetrahedral surface species; 2, tetrahedral surface clusters; 3, tetrahedral surface clusters of another type; 4, $\text{Mg}_3(\text{VO}_4)_2$. (c) Deconvolution of an experimental spectrum (2.6 wt.% V) into individual lines and the percentage of various V species on the MgO surface as a function of the total V content in $\text{V}_2\text{O}_5/\text{MgO}$ catalysts: 1, isolated tetrahedral surface species; 2, tetrahedral surface clusters; 3, tetrahedral surface clusters of another type; 4, $\text{Mg}_3(\text{VO}_4)_2$

on the type of support employed ($\sigma_{\text{iso}} = 480$ and 880 ppm for MgO and AlPO_4 , respectively) and $\Delta\sigma < 100$ ppm.

(b) For Al_2O_3 , ZrO_2 , $\text{ZrO}_2/\text{TiO}_2$, and SnO_2 , slightly distorted tetrahedral V species exist with σ_{iso} values ranging from 500 – 600 ppm and $\Delta\sigma < 200$ ppm.

(c) For SiO_2 and TiO_2 , distorted tetrahedral V species with one short V–O bond are formed. They exhibit axial anisotropy of chemical shielding with $\Delta\sigma < 600$ ppm.

An increase in V concentration (up to monolayer coverage) results in association of surface species. The following features associated with their ^{51}V NMR spectra can be noted.

(a) On MgO, AlPO_4 associated tetrahedral surface V species exhibit spectra with a fully anisotropic σ tensor, which points to a distortion of the VO_4 tetrahedra in these species ($\sigma_{\text{iso}} = 560$ – 570 ppm). The lines for such associated species are usually broader when compared with those for isolated species.

(b) For associated V species on Al_2O_3 , ZrO_2 , SnO_2 , and $\text{TiO}_2/\text{ZrO}_2$, fully anisotropic lines from distorted VO_4 surface tetrahedra are also observed ($\sigma = 700$ – 800 ppm). The widths of the lines are close to those for isolated V species on this surface.

(c) For associated V species on Al_2O_3 , ZrO_2 , $\text{TiO}_2/\text{ZrO}_2$, and SnO_2 of another type, lines with an axial anisotropy of the

shielding tensor arising from distorted octahedral V sites are observed ($\sigma_{\perp} = 320$ – 330 ppm, $\Delta\sigma = 600$ ppm).

(d) For associated V species on SiO_2 and TiO_2 , lines with an axial anisotropy of the shielding tensor arising from distorted octahedral V sites are observed ($\sigma_{\perp} = 290$ – 300 ppm, $\Delta\sigma > 900$ ppm).

A further increase of V concentration above monolayer coverage provides crystalline compounds [V_2O_5 on SiO_2 , TiO_2 , AlPO_4 , $\text{TiO}_2/\text{ZrO}_2$, and SnO_2 ; AlVO_4 on Al_2O_3 ; and $\text{Mg}_3(\text{VO}_4)_2$ on MgO].

Water adsorption changes the V coordination from tetrahedral to octahedral on SiO_2 and TiO_2 . In these cases, water molecules insert into the first coordination sphere of V. For V sites on ZrO_2 , AlPO_4 , $\text{TiO}_2/\text{ZrO}_2$, and SnO_2 , water molecules adsorb in the second coordination sphere, providing slight shifts of the ^{51}V NMR lines upon adsorption.

Addition of promoters, such as rhodium, titania, or zirconia (or impurities), results in notable changes in both the structure of the surface V species and their redistribution on the surface.

3.5 Vanadium Catalysts for SO_2 Oxidation

The active component of vanadium catalysts for SO_2 oxidation is known to consist of vanadium oxide and sulfates or pyrosulfates of alkali metals (K, Na, Cs are most commonly

Figure 8 Vanadium-51 NMR spectra of $\text{V}_2\text{O}_5/\text{TiO}_2$ catalysts (a) prepared by gas phase reaction of VOCl_3 with TiO_2 followed by subsequent hydration and removal of H_2O with a stream of He at 350°C and (b) prepared via impregnation with a solution of VOC_2O_4 : 1, anatase (all impurities less 0.1 wt.%); 2, TiO_2 (3.9 wt.% SO_4); 3, TiO_2 (3 wt.% Si); 4, TiO_2 (2.3 wt.% Na)

used) supported on porous materials such as silica or silica alumina. At ambient temperature the active component forms a thin vitreous film dispersed over the support. Under the reaction conditions ($400\text{--}500^\circ\text{C}$), the active component exists as a melt forming a very thin liquid layer on the support surface.

We present here the results of ^{51}V NMR studies of oxosulfatovanadates(V), chemical compounds formed between V_2O_5 and alkali pyrosulfates that are assumed to be present in the active component of these catalysts, as well as of $\text{V}_2\text{O}_5\text{--K}_2\text{S}_2\text{O}_7$ alloys and of commercial catalysts. Combined with other spectroscopic methods and kinetic studies, these results have helped to reveal the active sites in SO_2 oxidation and the mechanism of this catalytic reaction.^{1,20,21}

The spectra of oxosulfatovanadate(V) $\text{K}_3\text{VO}_2(\text{SO}_4)_2$, the alloy $\text{V}_2\text{O}_5 \cdot 3\text{K}_2\text{S}_2\text{O}_7$, and a commercial catalyst are presented in Figure 9. All oxosulfatovanadates(V) exhibit axial anisotropy of the chemical shielding tensor with parameters close to those for V_2O_5 . Thus the local environment of the vanadium atom in oxosulfatovanadates(V) is similar to that in V_2O_5 , where vanadium has a distorted octahedral (bipyramidal) oxygen atom environment with one V–O bond being considerably shorter than the others. Comparison of the spectrum of $\text{V}_2\text{O}_5 \cdot 3\text{K}_2\text{S}_2\text{O}_7$ alloy (Figure 9) with that for oxosulfatovanadate(V) $\text{K}_3\text{VO}_2(\text{SO}_4)_2$ shows that the former exhibits σ values close to those for oxosulfatovanadate(V). This indicates the same local environment for the V atoms in the glassy alloy and in crystalline oxosulfatovanadate(V).

The ^{51}V NMR spectra for various catalysts after treatment with a reaction gas mixture become quite similar and exhibit the same two lines, namely an almost isotropic line with $\sigma_{\text{iso}} = 520\text{--}560\text{ ppm}$ and a line with axial anisotropy of the shielding tensor. Only the relative intensities of the

Figure 9 Vanadium-51 NMR spectra of (1) oxosulfatovanadate(V) $\text{K}_3\text{VO}_2(\text{SO}_4)_2$; (2) the solid alloy $\text{V}_2\text{O}_5 \cdot 3\text{K}_2\text{S}_2\text{O}_7$; (3) the industrial catalyst BAV before treatment under the reaction conditions; (4) the same after treatment

two lines but not their character vary from one catalyst to another. In particular, the average chemical shifts for both the isotropic and anisotropic lines ($\sigma_{\perp} = 320\text{--}350\text{ ppm}$, $\sigma_{\parallel} = 1200\text{--}1300\text{ ppm}$) are almost the same for all the catalysts studied. This indicates that the active component in these catalysts is the same and is actually formed during the course of catalytic reaction.² Initially, catalysts arising from different preparations contain a variety of V sites. However, on interaction with the components of the reaction media only the two sites mentioned above are formed. The nearly isotropic line belongs to V atoms in a slightly distorted tetrahedral environment and can be attributed to vanadium bonded to the support. This line exhibits an increase in relative intensity with a decrease in the overall V content of the sample. Thus, the isotropic line belongs to V complexes on the SiO_2 surface.

Measurement of the catalytic activity for a series of samples with different contents of surface tetrahedral V has showed the latter to be inactive in SO_2 oxidation.²⁰

To elucidate the nature of the vanadium complexes which are active in SO_2 oxidation, ^{51}V , ^{17}O , ^{23}Na , ^{39}K , and ^{133}Cs NMR were combined with catalytic activity measurements of $\text{V}_2\text{O}_5\text{--K}_2\text{S}_2\text{O}_7$ melts and of catalysts with different amounts of the active component on SiO_2 .^{1,20,21}

Vanadium-51 NMR spectra of V_2O_5 and $\text{V}_2\text{O}_5 \cdot 3\text{Cs}_2\text{S}_2\text{O}_7$ alloy at temperatures below and above their melting points (Figure 10) demonstrate the spectrum of molten $\text{V}_2\text{O}_5 \cdot 3\text{Cs}_2\text{S}_2\text{O}_7$ (see *Molten Salts*) to be substantially broader than that of V_2O_5 . This means, that unlike V_2O_5 , where melting leads to a separation of the vanadium–oxygen layers and breaks them into relatively short fragments, in molten $\text{V}_2\text{O}_5 \cdot 3\text{Cs}_2\text{S}_2\text{O}_7$ substantially larger particles are formed.

Oxygen-17 NMR (see *Oxygen-17 NMR*) has also been used to characterize the melt of the active component in SO_2 oxidation at 500°C in the presence of an $\text{SO}_3 + \text{SO}_2 + \text{O}_2$ mixture, i.e. under typical conditions for the catalytic process in industry.^{1,20,21} Addition of V_2O_5 to $\text{K}_2\text{S}_2\text{O}_7$ leads to a shift and a broadening of the ^{17}O line, indicating V coordination with pyrosulfate anions. A more sophisticated analysis using a thermodynamic model of the ^{17}O linewidths has shown that at small vanadium concentrations approximately two to three pyrosulfate anions are coordinated to one V atom.

Figure 10 Vanadium-51 NMR spectra of (a) V_2O_5 and (b) of the alloy $V_2O_5 \cdot 3Cs_2S_2O_7$ (1) below the melting point (i.e. at $20^\circ C$) and (2) above the melting point ($670^\circ C$ and $370^\circ C$ for (a) and (b), respectively). Above: the structures formed in molten V_2O_5 and $V_2O_5 \cdot 3Cs_2S_2O_7$ alloy

Oxygen-17 NMR data also suggest a fast exchange between terminal and bridging oxygen atoms in the pyrosulfate anion which may occur via the reaction $S_2O_7^{2-} \rightleftharpoons SO_4^{2-} + SO_3$. The characteristic time τ during which this equilibrium is established is less than 10^{-3} s. Oxygen-17 and ^{51}V NMR data show that on addition of V_2O_5 to $K_2S_2O_7$, complexes are formed according to the reaction: $V_2O_5 + 3K_2S_2O_7 \rightleftharpoons 2K_3VO(SO_4)_3$. The increase in the ^{51}V and ^{17}O linewidths on increasing the V concentration suggests a further association of the V species leading to larger oligomers of the type shown in Figure 10. The large size of these oligomers makes their rotational diffusion very slow. Internal rotation of their fragments can also be hindered because of branching and linking of the oligomeric chains. Because of these factors, the ^{17}O and ^{51}V NMR lines of these species are too broad to be detected.

When supported on SiO_2 , the dimeric or oligomeric vanadium species can be more stabilized on the surface due to their interaction with Si-OH groups. These results agree well with studies of the catalytic activity of thin films of active melts on Pyrex glass and on SiO_2 , as well as with kinetic studies of SO_2 oxidation.²⁰

1 INTRODUCTION

The term 'adsorbed' implies concentrated at an interface. This article deals with the NMR of small molecules adsorbed, i.e. bound, to solid surfaces. (For a general introduction to adsorption and the properties of surfaces, see Adamson¹ or Somorjai.²) In addition to being of intrinsic scientific interest, adsorbed layers are of great practical importance in the areas of heterogeneous catalysis, separation science, and chromatography.

Molecules may bind to surfaces by any type of interaction, ranging from chemical bonding to van der Waals interaction. The case of chemical bonding is often called 'chemisorption', while the term 'physisorption' is sometimes used for weaker interactions. An adsorbed layer one molecule thick is called a 'monolayer' and thicker adsorbed deposits are called 'multilayers'. Clearly temperature is a major factor in determining the extent of adsorption, and appreciable adsorption will only be found when the interaction energy is greater in magnitude than kT .

NMR is the least sensitive of the common spectroscopic techniques, and thus the observation of adsorbed monolayers is dependent upon having a large amount of surface area in the NMR sample. The surfaces of highest specific area are those of activated carbon, and refractory oxides such as SiO_2 and Al_2O_3 . Because of their great importance as adsorbents, catalysts, and catalyst supports, the preparation of these has been much studied.^{3,4} These substances are readily prepared with specific surface areas of the order of hundreds of square meters per gram ($\text{m}^2 \text{g}^{-1}$). Their densities as powders are typically about 1 g cm^{-3} , so an NMR sample may contain hundreds of $\text{m}^2 \text{cm}^{-3}$. A monolayer of moderate sized molecules might contain $5 \mu\text{mol m}^{-2}$, so that the bulk concentration of an adsorbed monolayer can be of the order of 0.5 M. Such concentrations of sensitive high-abundance nuclei, e.g. ^1H , ^{19}F , and ^{31}P , can be observed in a single

scan with modern instrumentation. Those familiar with liquid NMR will find the effective sensitivity for adsorbed species to be considerably less, due to the much broader lines which arise for reasons noted below. None the less, high sensitivity nuclei are easily observed on such solids, and more difficult nuclei such as natural abundance ^{13}C can typically be observed in thousands or tens of thousands of scans. Often spin-lattice relaxation times for adsorbed molecules are appreciably shorter than for the same molecules in the liquid phase. This can make the signal averaging of large numbers of scans more feasible than might have been expected.

Another family of high area solids is the zeolites,⁵ crystals with internal pores of molecular size. The interior of these pores is equivalent to a high surface area, again typically of the order of hundreds of $\text{m}^2 \text{g}^{-1}$. Whether guest molecules inhabiting these pores can be said to be adsorbed is a matter of semantic convention. In this article the NMR of such guest molecules will be only briefly touched upon.

A large number of substances can be prepared in the $10 \text{ m}^2 \text{g}^{-1}$ range, and almost any solid can be prepared with $1 \text{ m}^2 \text{g}^{-1}$. Whether a high area preparation is stable with respect to loss of area by sintering depends mainly on the temperature. Typically the temperature must be kept below about one-half of the melting point to prevent substantial loss of area. A system of great practical interest is the supported metal catalyst.⁶ These catalysts consist of metal crystallites dispersed on a refractory oxide, such as silica or alumina. This technique permits a very high dispersion of the metal, with reduced tendency to sinter, and makes the most effective use of expensive platinum group metals. While the metal dispersion is extremely high, such catalysts typically contain a few per cent of metal by mass and have metal areas of 1 to $10 \text{ m}^2 \text{g}^{-1}$ of catalyst. Monolayers of high sensitivity nuclei are straightforward even at $1 \text{ m}^2 \text{g}^{-1}$; however, if one wishes to explore nuclei of low sensitivity, or small fractions of a monolayer, severe sensitivity problems eventually arise. One possible approach to this problem is to use the Curie law enhancement of NMR sensitivity at extremely low temperatures in the millikelvin range.⁷

In general, the preparation of high-area solids will result in an aggregate of randomly oriented crystallites. Some preparations, e.g. silica gels, will lack long-range order entirely. In a few favorable cases, high-area oriented samples can be prepared, e.g. in the case of lamellar clay particles by sedimentation.⁸

If one imagines a surface prepared by the sudden cleavage of a solid, it is evident that the surface may be viewed as a macroscopic radical with large numbers of 'dangling bonds', resulting from the disruption of the chemical bonds responsible for the integrity of the solid. Such a surface will be a very reactive entity and will be subject to structural rearrangement, which can lower its free energy, and to chemical reaction with its environment. Thus all metal surfaces (with the possible exception of Au) that have been in contact with the atmosphere will be covered by a layer of oxide. This layer may be a monolayer, or may be many layers thick. Similarly, oxide surfaces that have been exposed to the atmosphere normally have a monolayer of $-\text{OH}$ groups, resulting from their reaction with H_2O . This surface OH may be regarded either as the result of chemisorption of H_2O or as a normal constituent of oxide surface.

A 'clean' surface is one whose properties approximate the idealized cleaved crystal, at least as regards chemical

composition. (Many clean surfaces undergo rearrangement of their atoms to positions different from the bulk crystal.²) Clean surfaces are of much interest in fundamental surface science studies. In general, really clean surfaces are achieved only under ultrahigh vacuum conditions on areas of the order of 1 cm^2 ; adsorption on such surfaces is inaccessible to conventional NMR study at the present time. A possible exception to this statement is scattering experiments involving polarized atomic beams,^{9,10} which can yield nuclear relaxation data and possibly other NMR-like parameters. For the most part, however, present NMR studies involve surfaces that are at best partially clean. Thus, surface oxide can be removed from the noble metals by H_2 reduction, followed by thermal desorption of the resulting adsorbed H; surface OH can be largely removed from oxide surfaces by thermal treatment under vacuum. While not too attractive from the point of view of fundamental studies, the surfaces studied by NMR can easily be kept in a state similar to those used in practical applications for adsorption and catalysis, and NMR has substantial contributions to make to these fields.

The main features of the NMR of any sample will be determined by the mobility of the molecules studied. In this context, adsorbed layers are somewhat intermediate between liquid and solid samples. For many strongly chemisorbed samples, the adsorbed species are held in place by strong chemical bonds and are solids for NMR purposes. However, strong bonding to the surface does not necessarily imply localized bonding. For example, H atoms bind to most metal surfaces with an energy in excess of 200 kJ mol^{-1} , but in the case of the platinum group metals at room temperature they are mobile parallel to the surface on the NMR timescale, and are in some sense a two-dimensional fluid. Rotational motion of adsorbed molecules is also common, but the presence of the surface is likely to introduce greater anisotropy in this motion than would be observed in a liquid. Weakly bound physisorbed molecules are typically in rapid exchange with the gas phase, and average NMR properties will be observed. For high-area solids it will usually be the case that the adsorbed population is much larger than the gas-phase population, so that properties like chemical shifts will be dominated by those of the adsorbed phase, while the rapid exchange ensures that the motional properties of the layer appear liquid-like, both translationally and rotationally.

2 EARLY RESULTS

Not surprisingly, the first NMR studies of adsorbed species involved proton NMR^{11,12}. Since these predated high resolution solid state techniques, the possible experiments were broadline studies of immobile species, 'high-resolution' studies of mobile adsorbates, relaxation/linewidth measurements, and diffusion measurements by field gradient techniques. Examples of most of these exist from before 1960. For example, O'Reilly et al.¹³ observed that surface OH on silica and silica-alumina is chemically shifted with respect to liquid H_2O , and inferred from the temperature-independent Lorentzian lineshape that the OH forms a dilute randomly populated dipolar coupled system. Hickmott and Selwood¹⁴ studied the relaxation of water and several organics on various oxides, and showed the importance of surface paramagnetic species as relaxation agents. Fuschillo and Renton¹⁵ studied

the linewidth of methane on TiO_2 at low temperatures, and demonstrated the now well-known result that submonolayer amounts of physisorbed species do not become immobile until the temperature is well below the bulk freezing point.

In spite of these early successes, surface NMR in succeeding years proved somewhat disappointing. In general, very few chemical shifts proved to be measurable because of the large linewidths found for proton resonances. The sources of these linewidths were eventually realized to be rapid relaxation, especially by surface paramagnetic species, exchange with surface protons, heterogeneity of surface with respect to adsorption energetics, and inhomogeneous broadening from the nonzero magnetic susceptibility of irregular adsorbent particles; no proton linewidths less than 1 ppm were observed and much larger linewidths were common. Given the limited range of proton shifts, little of interest was shown regarding the structure and bonding of adsorbed molecules. Furthermore, with some notable exceptions,¹⁶ it turned out to be difficult to obtain information regarding molecular motion from relaxation studies. This was largely because of the difficulties of disentangling different relaxation processes, and the often dominant effect of paramagnetic surface species, in the presence of which correlation times may be determined more by electron relaxation than by adsorbate motions. The results of this early period are well summarized in the reviews by Packer¹⁷ and Pfeifer.¹⁸ Diffusion measurements, particularly in the context of guest molecules in zeolites, have recently been reviewed by Kärger et al.¹⁹

3 MULTINUCLEAR MAGNETIC RESONANCE

More possibilities were opened by the increasing availability of multinuclear and Fourier transform NMR equipment beginning in the 1970s. If, as it turns out, lines from adsorbed species will be at least a few ppm in width, chemical shifts should be observable for nuclei whose shift range is of the order of hundreds of ppm or more. An extreme example of this is the observation²⁰ of an 80 ppm shift for Ti^{4+} adsorbed from H_2O onto silica. In a more practical vein, the early 1970s saw the first natural abundance ^{13}C spectra of molecules in zeolites²¹ and physisorbed on silica²². Linewidths were a few ppm and it was possible to observe chemical shifts due, for example, to the hydrogen-bonding interaction of adsorbed acetone with surface hydroxyls. These works also demonstrated the possibility of measuring relaxation times separately for chemically different groups within a molecule. This could lead to simpler analysis of relaxation experiments for rigid molecules and the study of internal motions for others. In the early 1980s spectra were obtained for ^{15}N in a variety of molecules in zeolites²³ and adsorbed on SiO_2 ,²⁴ showing the advantages of studying the NMR of the atom which is the site of interaction between adsorbate and adsorbent. Relaxation studies of ^{17}O in H_2O on montmorillonite and kaolinite were performed.²⁵ These showed the desirability of measuring adsorbate correlation times in a system where strong quadrupolar interaction dominates the relaxation, and yielded surprisingly short correlation times for water in these systems, on the order of 10^{-11} s . Results to 1985 on multinuclear spectroscopy and relaxation measurements on adsorbed mobile molecules are comprehensively reviewed by Nagy, Engelhardt, and Michel.²⁶

4 HIGH-RESOLUTION SOLID STATE TECHNIQUES

The advent of high-resolution solid state NMR techniques in the 1960s and 1970s opened up new possibilities for the study of adsorbate systems. The most obvious of these is the identification of immobile chemisorbed species. The first use of these techniques by Kaplan et al.²⁷ was however a CP study of physisorbed benzene and toluene at low temperatures. Observation of an axially symmetric CSA powder pattern showed that benzene undergoes rapid rotation about the hexad axis, even at 77 K. Further experiments demonstrated that rapid cooling can trap molecules in a metastable isotropically rotating state at this temperature.

Magic angle spinning was first applied to surface problems by Stejskal et al.²⁸ in their study of CO₂ in zeolites. This showed that substantial line broadening which may arise from microscopic susceptibility variations in the adsorbate can be removed by MAS. Use of MAS in surface problems suffers from the conflicting requirements of atmospheric integrity, best achieved with sealed samples, and of excellent mechanical balance, which is likely to be degraded by the sealing process. This conflict was resolved in a semisatisfactory way in 1984.²⁹

The first use of multiple pulse line narrowing in surface studies was by Schreiber and Vaughan.³⁰ This permitted the measurement of the shielding anisotropy of surface protons on SiO₂; strong dipolar coupling to ²⁷Al prevented similar measurements on Al₂O₃. The combination of multiple pulse narrowing with MAS (CRAMPS), together with the use of higher magnetic fields, has recently been leading to growing success in the proton spectroscopy of adsorbed species.

5 ADSORBATES ON METALS

The resonance of hydrogen chemisorbed on platinum was first observed by Ito et al.³¹ Subsequently, the resonance of hydrogen has been observed on Cu, W, Ru, Rh, Pd, Os, Ir, and a few alloys, by these and other workers. (In the case of W, the cleanliness of the surface is questionable.) For all of the metals, large shifts are observed which cannot reasonably be chemical shifts and must therefore be Knight shifts. For Cu the shift is to high frequency, for the others to low frequency. With Ru–Cu bimetallic clusters³² the Knight shift of H on Ru decreases steadily as the Cu content is increased.

Platinum has been the most studied of these metals and it has been established that there is little difference between metallic powders and supported Pt catalysts. It has also been found that Knight shifts are smaller when the Pt particles are very small and when the adsorbed H covers a large fraction of the metal surface. As yet these trends have not received a satisfactory quantitative explanation in terms of the bonding between H and the metal surface. For all of the above metals the linewidth of the H resonance indicates that the hydrogen is mobile at room temperature. For those which have been studied to lower temperatures, motion generally ceases before liquid nitrogen temperature is reached.

¹³C NMR of CO chemisorbed on a metal was first studied by Duncan et al. on Rh.³³ Since then it has been studied on the remaining noble metals, and on bimetallic Pt–Rh particles. Much of this work is described in the reviews by Slichter³⁴ and Duncan.³⁵ On Ru and Rh an average shift is observed that corresponds to the known shifts of metal carbonyl complexes.

In static samples a broad powder pattern is observed with an anisotropy of some 400 ppm, corresponding to a linear carbonyl. On Rh, bridging carbonyl has also been observed. At room temperature, with the highest CO loadings, a narrow line appears from CO that is rotating isotropically on the NMR timescale. Thus the NMR of CO on Rh and Ru can be interpreted in terms of chemical shifts which are completely analogous to those observed in diamagnetic metal carbonyl complexes.

On the other hand, CO on supported Pt and Pd shows large high-frequency Knight shifts. Knight shifts are not observed for CO on colloidal platinum,³⁶ but it is not clear whether this is due to loss of metallic properties in the smaller particles or to interactions with the reagents used to stabilize the colloid. Supported Os and Ir show smaller high-frequency shifts and it is hard to be certain whether these are chemical or Knight shifts. Observations on Pt–Rh clusters³⁷ show that the Knight shift disappears above about 50% Rh, even though SEDOR measurements clearly show the presence of Pt in the surface layer of the particles.

The above results indicate that one must proceed with caution in interpreting the observed line positions of chemisorbed species on metals. For example, the metal (Rh) giving the largest Knight shift for adsorbed H gives no Knight shift for adsorbed CO. Thus in the absence of a reliable and comprehensive theory for Knight shifts of adsorbed species, every adsorption system must be examined carefully on its own merits.

6 ADSORPTION PROBES OF SURFACE SITES

The nature and concentration of specific types of site on solid surfaces has long been an area of interest, especially from the point of view of catalytic activity. These features can be probed spectroscopically by observing changes in the spectrum of a small molecule upon its binding to the surface. The archetypal example is the study of acid sites on oxide surfaces by IR spectroscopy of adsorbed amines;³⁸ pyridine, for example, gives distinct lines when physisorbed, protonated by a surface Brønsted acid, or coordinated to a surface Lewis acid.

This type of probing can obviously be done by NMR, which has the advantage that quantitative accuracy is in principle better. With IR spectroscopy it is generally difficult to be confident regarding the extinction coefficient of chemisorbed species, and there are often considerable uncertainties regarding path length and adsorbate concentration. Surface acids have thus been probed by direct proton NMR and by ¹³C, ¹⁵N, and ³¹P NMR of adsorbed amines and phosphines. Such attempts have been generally successful and are complementary to IR studies. Much of the work in this area has been reviewed by Freude.³⁹

Proton NMR cannot of course detect Lewis acids directly. For quantitative assessment of differing types of acid, ³¹P spectroscopy seems the most desirable. The high sensitivity of this nucleus permits spectra to be obtained in reasonable time periods by 90° pulse excitation, avoiding the need for cross polarization which may compromise quantitative accuracy. Most results have so far been obtained with trimethylphosphine as a probe; studies of a wider range of phosphorus bases seem likely in the future.

Solid surfaces may also contain basic sites; indeed, the same surface may simultaneously contain both strong acid and strong base sites. Probing these surfaces by NMR is less well developed, but a few results are available. For example, ^{13}C spectroscopy has been used to demonstrate, through the formation of surface bicarbonate from CO_2 , the unsurprising result that surface OH on MgO is basic.

7 SURFACE HYDROXYL GROUPS

As mentioned above, all oxides are covered with a layer of $-\text{OH}$ groups, which may in a formal sense be regarded as the result of water chemisorption on an ideal oxide surface. The surface chemistry of oxides in their normal state is largely determined by the properties of these hydroxyl groups. The properties of these hydroxyl groups vary from one oxide to another, and the same oxide may show differing types of $-\text{OH}$ groups, reflecting different exposed crystal planes, or different structural arrangements. Many of the classic NMR investigations^{13,30} have dealt with these groups, and the literature of studies by IR spectroscopy is particularly voluminous. Much of the IR literature and some of the NMR investigations have been reviewed by Morrow.⁴⁰ A recent review by Mastikhin et al.⁴¹ is devoted to NMR studies, particularly of recent results obtained through magic angle spinning.

8 CHEMICAL REACTION IN ADSORBED LAYERS

Adsorbed layers are the site of heterogeneous catalysis and hence reaction in these layers is a topic of immense scientific, technical, and economic interest. NMR studies of such reactions may proceed in two rather different ways. For reasonably rapid reactions of systems that are in equilibrium under NMR conditions, the familiar methods of shift, relaxation, and lineshape analysis may be employed, as in solution NMR. The possibilities for this type of study of adsorbed systems have been reviewed by Resing.⁴² On the other hand, slow reactions may easily be studied by recording NMR spectra as a function of time. A sealed NMR tube is in many ways an ideal contamination-free reactor. Reaction studies have been greatly advanced by CP MAS techniques, which permit the potential observation of a wide range of reaction products and intermediates.

For species reacting at a convenient rate at room temperature, e.g. the reaction of trimethyl phosphite with the silica surface,⁴³ straightforward MAS spectroscopy as a function of time can provide kinetic data for the surface reaction processes. For systems that are only reactive above room temperature, a 'quick and dirty' technique is to heat samples for controlled periods of time at the reaction temperature, and then cool to room temperature for NMR observation.⁴⁴ While this method provides useful insights, it suffers from uncontrolled conditions during the heating and cooling phases, together with uncertainties about desorption.

Clearly this type of study awaits the development of reliable high-temperature sealable MAS equipment, and recent progress has been made in this direction by Haw and coworkers.⁴⁵ Unfortunately, sealed-sample MAS is always

open to uncertainties arising from the possibility of desorption when the sample is heated above its preparation temperature. There seems no obvious way of combining the traditional catalytic flow reactor with MAS NMR. For the case of static samples, an NMR-compatible flow reactor has been designed by Reimer and co-workers.⁴⁶

9 STRUCTURE OF ADSORBED SPECIES

NMR of solids has the possibility of yielding direct structural information through measurement of dipolar interactions. Since the structures of chemisorbed species are in general not readily determined, this is a powerful possibility. The fundamental problem is that the motional state of observed species is not known a priori, and it will be unclear whether an observed dipolar coupling should be corrected for motional averaging. Thus, early observations of Pake doublets from adsorbed water⁸ (see also bibliography in Pfeifer¹⁸) generally gave splittings much too small to correspond to static H_2O molecules. These results were therefore not used to infer structural information, but were instead interpreted to give motional information based on the assumption of the known structure of isolated water molecules. In a system where significant structural changes have occurred due to chemical reaction, it seems necessary to demonstrate that observed dipole couplings are independent of temperature, or to give some other evidence for lack of motion, before inferring structural parameters.

Duncan and Vaughan⁴⁷ were among the first to use modern solid state methods to determine dipolar couplings in adsorbed layers. Their H-C dipolar modulation studies of adsorbed formic acid gave essentially the same coupling as observed in crystalline formates. A deviation from the expected bond length based on X-ray measurements of calcium formate was attributed to motion, even though the couplings in the adsorbed layer appeared temperature independent.

More recently, Slichter and co-workers³⁴ have applied spin echoes and SEDOR to measure homonuclear and heteronuclear dipole couplings in adsorbed layers, and to attempt to measure the bond length between adsorbate and surface. The latter endeavor is complicated by the possibility, with heavy nuclei such as ^{195}Pt , of indirect ('scalar') couplings of magnitudes comparable to the dipolar couplings.

In principle, dipolar couplings could be estimated from relaxation or NOE measurements. In practice, the often dominant effects of surface paramagnetic impurities, and the general anisotropy of motion in adsorbed layers, render this a complicated and unattractive prospect.

A less direct way of obtaining structural information from dipolar couplings is by the observation of multiple quantum coherence, from which the size of coupled spin aggregations may be inferred. This was first applied to surface problems by Slichter and co-workers,⁴⁸ and has recently been reviewed by Hwang and Gerstein.⁴⁹

10 MOTION IN ADSORBED LAYERS

As mentioned in the previous section, structural and motional determinations are a coupled problem pair. In general

the study of motions is simpler, because for many adsorbed systems the assumption of known structures in the adsorbed layer will be chemically tenable.

As indicated above, interpretation of relaxation is difficult in adsorbed systems. More reliable motional information is likely to be obtained by the observation of approximately local molecular properties, such as chemical shift anisotropies, dipolar splittings, and quadrupolar couplings. Thus the first CP study²⁷ of an adsorbed layer revealed an axially symmetric CSA powder pattern for physisorbed benzene at 77 K. This indicated rapid rotation about the sixfold axis at a temperature well below that at which such rotation occurs in the solid.

Subsequently, Resing and co-workers used analysis of CSA powder patterns to determine the motions of various adsorbed species, such as anchored phenyl groups.⁵⁰ Sindorf and Maciel⁵¹ used cross polarization rates as an indicator of average C–H dipolar coupling to study the dynamics of long alkyl chains bound to silica surfaces. Yannoni et al.⁵² observed C–C dipolar splittings in doubly-labeled benzene to study its structure and motions on a Pt–Al₂O₃ catalyst. The use of deuterium quadrupolar powder patterns to study motions in adsorbed phases is exemplified by the elegant studies of Luz et al.⁵³ on methyl amines sorbed in zeolites.

1 INTRODUCTION

Amphiphilic molecules (surfactants) consist of a polar, often charged, headgroup linked to one or two hydrocarbon, usually alkyl, chains. In the presence of water and possibly additional components, such as long-chain alcohols, alkanes, or simple electrolytes, surfactants spontaneously assemble into finite aggregates (micelles) or build up structures that extend indefinitely in one, two, or three dimensions. This gives rise to numerous liquid crystalline phases, differing in their macroscopic translational and rotational symmetries and displaying a fascinating geometrical and topological variety in their self-assembled microstructure.^{1–6} The structural and dynamic characterization of these phases and the rationalization of their microstructure and phase behavior in terms of intermolecular and interaggregate forces is a challenging task. The importance of amphiphilic liquid crystals derives partly from their biological significance and diverse technical applications. In a more general context, amphiphilic liquid crystals are prime examples of complex fluids (soft matter) and their study has proven to be a rich source of fundamental knowledge.

Nuclear magnetic resonance has contributed more than any other technique to the understanding of amphiphilic liquid crystals. The NMR experiments used in this field are basically of three kinds: lineshape, diffusion, and relaxation studies. Spectral lineshapes from powder samples are now used routinely to distinguish among cubic, uniaxial, and biaxial phases (see *Lytotropic Liquid Crystalline Samples*). Pulsed field gradient spin echo experiments can, under favorable conditions, provide the principal components of the macroscopic diffusion tensor for various molecular components (see *Liquid Crystalline Samples: Diffusion*). Nuclear spin relaxation can provide detailed information about structure and dynamics on a wide range of length and time scales. As compared with lineshapes and diffusion, spin relaxation is a less direct source of information and therefore requires a more elaborate theoretical framework for its interpretation. On the other hand, liquid crystals can yield a large amount of relaxation data, including a variety of spin relaxation rates associated with high-rank

polarization modes, and their dependence on Larmor frequency and sample orientation.

The first spin relaxation studies of amphiphilic liquid crystals appeared in the late 1960s. In a seminal contribution from the early years, Charvolin and Rigny⁷ identified the three main sources of spin relaxation as: (i) local, orientationally restricted motions (rotational isomerization in the case of surfactant chains); (ii) molecular diffusion over curved interfaces; and (iii) collective director fluctuations. It was not until the 1980s, however, that improved instrumental capabilities, new pulse techniques, and advances in relaxation theory established nuclear spin relaxation as a major source of quantitative information about amphiphilic liquid crystals.^{8,9} This is a highly interdisciplinary field of study where ideas and methods are continuously exchanged with several related fields, most notably molecular (thermotropic) liquid crystals and phospholipid bilayers (see Related Articles in Section 6).

2 RELAXATION MECHANISMS AND EXPERIMENTAL METHODS

2.1 General Considerations

The proton is not an ideal nucleus for relaxation studies of amphiphilic liquid crystals due to the complex relaxation behavior of the strongly coupled aliphatic chain protons, the rapid exchange of labile headgroup protons, and the contribution from intermolecular dipole–dipole couplings. Fortunately, there are several other nuclei more suitable for relaxation studies, e.g. ²H or ¹³C in surfactant chains, and ²H or ¹⁷O in water. For studies of microstructure, the choice is restricted to nuclei that are effectively confined to the interface, i.e. surfactant headgroup nuclei (e.g. ¹⁴N), counterion nuclei (e.g. ²³Na), or ²H nuclei in the α -position of the surfactant chain.

Despite important advances in recent years, the complex spin-dynamical behavior of quadrupolar nuclei and coupled spin- $\frac{1}{2}$ nuclei (such as ¹³C¹H₂) in liquid crystals has not yet been fully explored. Since most of the relevant nuclei have spin $I > \frac{1}{2}$, we emphasize quadrupolar relaxation. With the exception of $I \geq \frac{3}{2}$ nuclei, most pulse techniques for relaxation studies of anisotropic systems have been developed in other fields (see *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods*); only a brief discussion is included here.

2.2 Quadrupolar Relaxation

Nuclei with $I \geq 1$ are coupled to the molecular degrees of freedom via the interaction of their electric quadrupole moment with the electric field gradient (EFG) generated by the surrounding charge distribution (see *Quadrupolar Interactions*). The first-order effect of the quadrupole coupling is to split the resonance into $2I$ equidistant lines (see *Quadrupolar Nuclei in Solids*). The quadrupole splitting occurs in all noncubic phases and contains information about the orientational order in the phase. In all but the simplest cases, however, the quadrupole splitting yields a product of order parameters, associated with different orientational

degrees of freedom, which cannot be separated without recourse to additional (e.g. relaxation) data.

The principal second-order effect of the quadrupole coupling is to induce spin relaxation (see *Relaxation Theory for Quadrupolar Nuclei*). All information about liquid crystal structure and dynamics that can be derived from quadrupolar relaxation rates is contained in the three lab-frame spectral densities (LFSDs) $J_{kk}^L(k\omega_0; \Omega)$ with $k = 0, 1, 2$:

$$J_{kk}^L(k\omega_0; \Omega) = \int_0^\infty d\tau \cos(k\omega_0\tau) [\langle V_k^{L*}(0) V_k^L(\tau) \rangle - |\langle V_k^L \rangle|^2] \quad (1)$$

which are functions of the magnitude $B_0 = \omega_0/\gamma$ and orientation Ω (with respect to the liquid crystal) of the external magnetic field. The quantity within brackets in equation (1) is the time autocorrelation function of the k th spherical component V_k^L (in the lab frame) of the EFG tensor. The secular ($k = 0$) spectral density contains information about motions on all timescales (within the motional narrowing regime), while the nonsecular ($k = 1, 2$) spectral densities are affected only by motions on the timescale $1/\omega_0$ or faster. To determine the three individual LFSDs at a given magnetic field, one needs to measure at least three independent relaxation rates.

A system of spin I nuclei admits nonequilibrium states with magnetic tensor polarization of rank $k = 1, 2, \dots, 2I$ and coherence order $q = 0, \pm 1, \dots, \pm k$. The spin system can thus be described in terms of $(2I + 1)^2 - 1$ state multipoles¹⁰ of rank k and projection index q . The axial ($q = 0$) multipole components, referred to as polarizations or alignments, are the generalizations of longitudinal magnetization ($k = 1, q = 0$). The remaining ($q \neq 0$) multipole components, referred to as q quantum coherences, are the generalizations of transverse magnetization ($k = 1, q = \pm 1$). The effect of hard radiofrequency pulses is simply to rotate the state multipoles, i.e. to mix the quantum order q without affecting the tensor rank k , whereas evolution under the (fluctuating) quadrupolar Hamiltonian mixes the rank without affecting the quantum order.¹¹

In noncubic liquid crystals, the evolution of the polarizations involves $2I$ generalized longitudinal relaxation rates which depend on the two nonsecular LFSDs. (This dependence is linear for $I = 1$ and $I = \frac{3}{2}$, but nonlinear for $I \geq \frac{5}{2}$). The principal longitudinal relaxation experiments are the classical inversion–recovery and Jeener–Broekaert experiments¹² and their generalizations.¹³

The evolution of the coherences involves $I(2I + 1)$ generalized transverse relaxation rates, some of which may be degenerate. The homogeneous linewidths of satellite peaks, i.e. spectral lines that exhibit a first-order quadrupolar shift, are linear combinations of all three LFSDs, whereas the widths of the unshifted central peaks are linear combinations of the two nonsecular LFSDs. (This linear dependence of the linewidths on the LFSDs holds only if the quadrupole splitting is large compared with the nonsecular linewidth.)

Accurate measurements of homogeneous linewidths require echo experiments to refocus dephasing due to spatial inhomogeneities in the magnetic field and in the (static) quadrupole coupling (usually due to imperfect alignment). Whereas either 1D or 2D experiments can be performed on $I = 1$ nuclei,

Table 1 Number of Independent Spin Relaxation Rates for Quadrupolar Nuclei in Non-Cubic Liquid Crystals

Relaxation rate	$I = 1$	$I = \frac{3}{2}$	$I = \frac{5}{2}$	$I = \frac{7}{2}$
Longitudinal	2	3	5	7
Transverse ^a	2	2	6	10
secular	1	1	3	6
nonsecular	1	1	3	4

^aFrom homogeneous linewidths only.

2D experiments are indispensable for $I \geq \frac{3}{2}$ nuclei. The nonsecular central linewidths, associated with the $-q/2 \leftrightarrow q/2$ transitions, are obtained from 2D spin echo experiments, while the secular satellite linewidths are obtained from 2D quadrupolar echo experiments.^{14–16} Table 1 lists the number of distinct relaxation rates that can be measured for different quadrupolar nuclei.

2.3 Dipolar Relaxation

For studies of local surfactant dynamics one can use the ^{13}C nuclei in the alkyl chain, which are relaxed by the dipole–dipole coupling to directly bonded protons. The relaxation behavior of a weakly coupled AX_2 spin system such as $^{13}\text{C}^1\text{H}_2$ is complicated by ^{13}C – ^1H cross relaxation, which is the basis of the nuclear Overhauser effect (NOE), and by cross correlation (interference) between the two C–H pairs which leads to the formation of high-rank polarization (three-spin order).¹⁷ The ^{13}C longitudinal relaxation becomes effectively exponential, however, if the protons are decoupled by strong irradiation and if relaxation within the (strongly coupled) proton spin system quenches the development of high-rank polarization.¹⁸ The ^{13}C inversion–recovery and steady-state NOE are then determined by the three LFSDs $J_{kk}^L(\omega_C + (k - 1)\omega_H; \Omega)$ with $k = 0, 1, 2$, defined as in equation (1) but with V_k^L now denoting the spherical components of the ^{13}C – ^1H dipole–dipole interaction tensor.

2.4 Relaxation Anisotropy and Phase Symmetry

For a system as complex as an amphiphilic liquid crystal, the LFSDs obtained from spin relaxation experiments are usually not amenable to direct physical interpretation without recourse to detailed structural and dynamic models. However, by transforming the lab-frame components V_k^L of the interaction tensor to a crystal-fixed frame, the LFSDs can be decomposed as

$$J_{kk}^L(\omega_k; \Omega) = \sum_{n,p} F_{knp}(\Omega) J_{np}^C(\omega_k) \quad (2)$$

where $\omega_k = k\omega_0$ for quadrupolar relaxation and $\omega_k = \omega_A + (k - 1)\omega_X$ for longitudinal dipolar relaxation of nucleus A coupled to nucleus X. When the time reversal invariance present in all dynamic models of interest has been taken into account there are 15 crystal-frame spectral densities (CFSDs) $J_{np}^C(\omega_k)$, defined in analogy with equation (1). Depending on the rotational symmetry of the liquid crystal, some of these CFSDs

Table 2 Number of Independent Crystal-frame Spectral Density Functions (N) and Second-rank Order Parameters (n_2) for Different Crystallographic Point Groups

Phase	Point group	N	n_2
Isotropic fluid	K_h	1	0
Cubic	O_h	2	0
Lamellar, nematic U, hexagonal	$D_{\infty h}, D_{6h}$	3	1
Tetragonal, rhombohedral	D_{4h}, D_{3d}	4	1
Rectangular, orthorhombic, nematic B	D_{2h}	6	2
Oblique	C_{2h}	9	3
Monoclinic	C_i	15	5

may vanish or be linearly dependent. Taking the rotational symmetry into account, equation (2) can be expressed as¹⁹

$$J_{kk}^L(\omega_k; \Omega) = \sum_{\lambda} F_{k\lambda}(\Omega) J_{\lambda}^C(\omega_k) \quad (3)$$

with the composite index $\lambda = (\alpha, \mu, \mu')$ labeling the irreducible representations α of the liquid crystal point group and the independent subspaces μ of α . The irreducible CFSDs $J_{\lambda}^C(\omega_k)$, constructed from symmetry-adapted tensor components, constitute the complete model-independent information content of a fixed-field spin relaxation study of a liquid crystal.¹⁹ The number N of independent CFSD functions is given in Table 2 for liquid crystals of different symmetry. By measuring three linearly independent spin relaxation rates at N different orientations Ω of the (homeotropically aligned) liquid crystal, one can thus determine the $3N$ quantities $J_{\lambda}^C(\omega_k)$. This relative wealth of model-independent information (as compared to isotropic fluids) imposes severe constraints on models of structure and dynamics.

In isotropic powder samples, the relaxation of the central peak ($-q/2 \leftrightarrow q/2$ transition) for noncubic phases and of the single peak for cubic phases is governed by the isotropically averaged (by interdomain exchange) LFSD:¹⁹

$$J_{\text{iso}}^L(\omega_k) = \frac{1}{5} \sum_{\alpha} d_{\alpha} \sum_{\mu} J_{\alpha\mu\mu}^C(\omega_k) \quad (4)$$

with d_{α} being the dimension of the irreducible representation α .

While the rotational symmetry of a liquid crystal is determined by its crystallographic point group, the observable manifestations of this symmetry depend on the tensor rank of the measured physical property. The powder lineshape, being determined by the (motionally averaged) second-rank EFG tensor, can only distinguish between effectively isotropic, uniaxial, and biaxial symmetries. This is reflected in the number n_2 of independent second-rank order parameters (see Table 2). The CFSDs, involving products of two components V_k^L of a second-rank tensor, can be decomposed into terms transforming as tensors of rank 0, 2, and 4; hence there are $N = 1 + n_2 + n_4$ independent CFSDs.¹⁹ Phases with the same ‘second-rank symmetry’ can thus have different relaxation behavior (see Table 2). On the other hand, since spin relaxation does not involve a higher tensor rank than 4, the relaxation anisotropy is of the same form for hexagonal phases (sixfold symmetry) as for lamellar and uniaxial nematic phases (full cylindrical symmetry). Since the second-rank spherical components V_n transform according to the

Figure 1 Anisotropy of the nonsecular lab-frame spectral densities obtained from the counterion ^{23}Na relaxation in the hexagonal²⁰ and (nonclassical) lamellar²¹ phases of the sodium dodecyl sulfate/decanol/water system at 25 °C. The curves are fits according to equation (5)

irreducible representations (A_1 , E_1 , and E_2) of the point group $D_{\infty h}$, the relaxation anisotropy for these phases takes the form:

$$J_{kk}^L(\omega_k; \beta) = \sum_{n=0}^2 (1 - \delta_{n0}/2) \{ [d_{kn}^2(\beta)]^2 + [d_{k-n}^2(\beta)]^2 \} J_{nn}^C(\omega_k) \quad (5)$$

where the $d_{kn}^2(\beta)$ are reduced Wigner functions and β is the angle between the magnetic field and the symmetry axis of the phase. Figure 1 shows the nonsecular ^{23}Na relaxation anisotropy of counterions in a hexagonal phase²⁰ and in a lamellar phase with disrupted bilayers.²¹ In each case, the fit of equation (5) to the LFSD data yields the six model-independent CFSDs $J_{nn}^C(k\omega_0)$ with $k = 1, 2$ and $n = 0, 1, 2$.

2.5 Relaxation Dispersion and Low-Frequency Dynamics

The dynamic processes responsible for spin relaxation in amphiphilic liquid crystals take place mainly on three time scales: local, restricted motions (1–100 ps), molecular

diffusion over curved interfaces (1–10 ns), and collective processes (> 100 ns). While the local motions are usually in the extreme narrowing limit, the dispersion of the surface diffusion contribution to the nonsecular spectral densities is in the frequency range ($\omega_0/2\pi \approx 1$ –100 MHz) accessible by conventional relaxation experiments. While the secular spectral density $J_{00}^L(0)$ reflects motions on all timescales, special techniques are required to investigate the low-frequency dispersion associated with collective processes.

Two methods are available for probing the secular LFSD $J_{00}^L(\omega)$ in the kHz frequency range. For $I = 1$ nuclei, the quadrupolar echo train $(\pi/2)_x - [\tau - (\pi/2)_y - \tau]_n$ yields an effective spectral density²²

$$\begin{aligned} & \frac{8}{\pi^2} \sum_{n=0}^{\infty} (2n+1)^{-2} J_{00}^L \left((2n+1) \frac{\pi}{2} \omega_p \right) \\ &= J_{00}^L(0) \left[1 - \omega_p \tau_c \tanh \left(\frac{1}{\omega_p \tau_c} \right) \right] \end{aligned} \quad (6)$$

with $\omega_p = 1/\tau$ the pulse train frequency. The second form in equation (6) holds only if $J_{00}^L(\omega)$ is Lorentzian, with correlation time τ_c . Relaxation in the presence of a spin lock field B_1 yields, in a $T_{1\rho}$ experiment on $I = 1$ nuclei, an effective spectral density given approximately by²³

$$\frac{(2\Omega_1)^2}{\omega_Q^2 + (2\Omega_1)^2} J_{00}^L \left(\sqrt{\omega_Q^2 + (2\Omega_1)^2} \right) \quad (7)$$

with $\Omega_1 = \gamma B_1$ and ω_Q the static (residual) quadrupole frequency. If $J_{00}^L(\omega)$ is Lorentzian, equation (7) has a maximum of $J_{00}^L(0)(\sqrt{1+x^2}+x)^{-2}$ at $\Omega_1 = (\omega_Q/2)(1+x^{-2})^{1/4}$, with $x = \omega_Q \tau_c$.

A much wider frequency range, from the conventional MHz range down to ca. 100 Hz, can be explored by the field cycling technique²⁴ (see *Field Cycling Experiments*). Unfortunately, this technique is not applicable to rapidly relaxing quadrupolar nuclei; so far only ^1H field cycling studies of amphiphilic liquid crystals have been reported. As seen from Figure 2, the entire dispersion due to collective processes can be obtained in this way.²⁵

3 ORDER AND DYNAMICS AT THE MOLECULAR LEVEL

3.1 Water and Counterions

Amphiphilic interfaces induce only small and short-ranged perturbations of the strongly hydrogen-bonded network in liquid water. Since the surface-induced orientational order and reorientational anisotropy are weak, the three LFSDs are equal, $J_{kk}^L(\omega_k) = J_{00}^L(0)$, and the spin relaxation exhibits neither anisotropy nor dispersion. Water reorientation in the first molecular ‘layer’ is typically slowed down by a factor of two to three, and there is no evidence for long (> 100 ps) water residence times in any amphiphilic system. Water ^2H and ^{17}O relaxation rates thus report essentially on the fast, local water dynamics, which are insensitive to variations in microstructure.^{26,27}

Figure 2 Dispersion of the longitudinal relaxation rate R_1 of surfactant chain protons in powder samples of the lamellar, hexagonal, and cubic phases of the potassium dodecanoate/ D_2O system at 70°C ²⁵

Counterion relaxation rates reflect fast, local motions as well as slower motions, e.g. diffusion over curved interfaces. The relative contributions from fast and slow motions can be estimated²⁶ as $\langle \chi^2 \rangle \tau_f$ and $\langle \chi^2 \rangle \tau_s$, respectively, where $\langle \chi^2 \rangle$ is the mean square quadrupole coupling constant (QCC), $\langle \chi \rangle$ the residual QCC (averaged by the fast motions), and τ_f and τ_s the effective correlation times. As in the case of water, the residual anisotropy is weak ($\langle \chi \rangle^2 \ll \langle \chi^2 \rangle$), and the fast-motion contribution to the LFSDs is independent of orientation and frequency.²⁰ However, the ratio τ_s/τ_f is typically (in the presence of curved interfaces) an order of magnitude larger for counterions than for water, making the fast and slow contributions comparable. For atomic counterions, where the EFG is of intermolecular origin, the local motion contribution $\langle \chi^2 \rangle \tau_f$ and the residual QCC $\langle \chi \rangle$ depend markedly on the molecular details of the interface region, but in a way that is not readily captured by simple models.

3.2 Surfactant Molecules

Rotational isomerization in surfactant alkyl chains is too fast (< 10 ps) to produce a dispersion in the ^2H or ^{13}C relaxation.^{8,28} This introduces a certain model dependence in the interpretation,^{28–30} although constraints are imposed by the individual bond order parameters deduced from static dipole or quadrupole couplings.⁸ On a longer timescale (typically, 0.1–1 ns), the conformationally averaged surfactant molecule undergoes restricted reorientation within the aggregate. This motion can produce a high-field dispersion in the ^{13}C relaxation (which involves the Larmor frequency of ^1H), whereas the ^2H relaxation is usually in the extreme narrowing limit.²⁸ The relaxation anisotropy is expected to be weak for alkyl chain nuclei, but can be substantial for headgroup nuclei in double-chain surfactants.²⁸ The overall motion of surfactants is usually modeled as rotational diffusion of a symmetric top in a uniaxial potential of mean torque (see *Liquid Crystalline Samples: Relaxation Mechanisms*).

The relaxation of a surfactant nucleus induced by the intermolecular dipole coupling with a nuclear or electron spin in a counterion can, in certain cases, provide information about

Table 3 Relaxation Processes in Amphiphilic Liquid Crystals

Dynamics	Order fluctuations	Director fluctuations
Single-molecule	Diffusion in order gradient	Diffusion on curved interface Diffusion in nematic director field
Collective	Critical fluctuations	Micelle reorientation Nematic director fluctuations Interface shape fluctuations

the spatial distribution of the surfactant nucleus with respect to the interface.^{8,31} The interpretation of such relaxation data is, however, strongly model dependent.³²

4 MICROSTRUCTURE AND DIFFUSION

4.1 Fluctuating Local Anisotropy

Much of the intricate spin relaxation behavior of complex fluids such as amphiphilic liquid crystals can be rationalized in terms of a unifying concept: the fluctuating local anisotropy. On longer timescales, the net effect of the fast, local motions (see Section 3) is to project the quadrupole (or dipole–dipole) interaction tensor onto an axis, the (local) director, which usually coincides with the local interface normal. The motionally averaged, or projected, interaction tensor is proportional to the second-rank ordering tensor $\mathbf{S}$, with three independent components in the usual case of local uniaxial symmetry. In the director frame, $\mathbf{S}$ is diagonal and the three independent variables are the principal order parameter S and the set Ω of two angles that specify the director orientation (with respect to the crystal axes).

All relaxation processes, apart from the local motions, can be classified as either local order fluctuations, which modulate the order parameter $S(t)$, or local director fluctuations, which modulate the director orientation $\Omega(t)$. Each of these classes can be further subdivided according to whether the fluctuations are due to single-molecule dynamics (translational diffusion) or to collective processes, involving many molecules. Among the relaxation processes listed in Table 3, those in the director fluctuation class are generally most important. Diffusion of water or counterions between interface ($S \neq 0$) and bulk ($S = 0$) regions³³ is usually an inefficient relaxation process,^{21,34} and critical order fluctuations³⁵ occur only near phase transitions.

4.2 Diffusion on Curved Interfaces

All amphiphilic liquid crystalline phases, save the lamellar one, are built from curved interfaces, over which surfactants

and counterions diffuse freely. (The long-range Coulomb interaction effectively reduces the dimensionality of the diffusion space for counterions to two.^{21,33,34}) This constitutes an efficient relaxation process of the director fluctuation type, which can yield quantitative information about the interface geometry (microstructure) and the surface diffusion coefficient, D_s . Typically, the microstructure involves radii of curvature of the order 1–2 nm, while $D_s \approx (0.1–1) \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. The associated correlation times are thus in the 1–10 ns range, which places the relaxation dispersion in the conventional MHz range of Larmor frequencies. We now consider how surface diffusion induced quadrupolar spin relaxation can be exploited in the various phases.

4.3 Hexagonal Phases

The normal hexagonal phase is built from cylindrical surfactant aggregates of indefinite length, arranged on a two-dimensional hexagonal lattice. Since the director, i.e. the cylinder surface normal, is everywhere perpendicular to the sixfold symmetry axis of the phase, surface diffusion around the cylinder contributes to only one of the three CFSDs, i.e.

$$J_{nn}^C(k\omega_0) = J_{\text{loc}} + \delta_{n2} \langle \chi \rangle^2 \frac{3}{8} \frac{\tau_s}{1 + (k\omega_0\tau_s)^2} \quad (8)$$

with the correlation time $\tau_s = R^2/(4D_s)$, and R the diffusion radius. In addition, the adiabatic ($k = 0$) CFSDs have contributions from long-wavelength cylinder undulations.

With R obtained from the X-ray Bragg spacing, the surface diffusion coefficients D_s of surfactants and counterions can be accurately ($\pm 10\%$) determined from the nonadiabatic ($k = 1, 2$) CFSDs obtained from the nonsecular relaxation anisotropy (see Figure 1) at a single magnetic field.^{20,36} In reversed hexagonal phases, the radius of the aqueous cylinders can be varied in a controlled way, allowing a direct verification of the R^2 scaling of the correlation time.³⁴

4.4 Lamellar Phases

In a classical lamellar phase, with periodically stacked, planar surfactant bilayers of indefinite lateral extent, one expects neither anisotropy nor dispersion in the nonsecular LFSDs, since in the absence of interface curvature, $J_{nn}^C(k\omega_0) = J_{\text{loc}}$ for $k = 1, 2$. (The secular LFSD, however, should exhibit anisotropy due to long-wavelength bilayer undulations; see Section 5.3). Spin relaxation is therefore a sensitive curvature probe for lamellar phases; any deviation from the classical microstructure is unambiguously revealed by the relaxation anisotropy and dispersion produced by molecular diffusion over curved interfaces.

In the lamellar phase of the sodium dodecyl sulfate/decanol/water system, the ^{23}Na relaxation (see Figure 1) provides direct evidence for a highly curved interface at low decanol content,²¹ whereas at higher decanol content the microstructure is classical. The relaxation behavior is consistent with a microstructure of ribbon-like aggregates, arranged on the smectic planes so as to preserve the uniaxial symmetry of the lamellar phase. The three CFSD functions $J_{nn}^C(\omega)$ can then be related to two irreducible (D_{2h}) ribbon-frame spectral density functions associated with surface diffusion around the ribbon-like aggregate.

4.5 Uniaxial Nematic Phases

Two types of uniaxial nematic phase occur in amphiphilic systems:⁴ the calamitic (N_C) and discotic (N_D) phases, built from orientationally ordered nonspherical micellar aggregates of approximately prolate and oblate spheroidal shape, respectively. To understand these phases, one needs to quantify the size of the micelles and their long-range orientational order.

Nuclear spin relaxation studies can, in principle, yield the micelle dimensions as well as the second-rank nematic order parameter.³⁷ Two difficulties are encountered, however. First, the fast magnetic alignment of nematic fluids precludes relaxation anisotropy measurements with conventional methods. This experimental problem can be partly overcome by sample spinning techniques (see *Spinning Liquid Crystalline Samples*). The second difficulty is intrinsic: spin relaxation is induced not only by molecular diffusion over the micelle surface, but also by rotation of the micelle around its symmetry axis and restricted tumbling of this axis. While the three CFSDs associated with spheroidal surface diffusion and single-micelle reorientation (in a uniaxial potential of mean torque) can be accurately calculated,³⁸ it is more difficult to describe the cooperative reorientation modes in the transition zone between the single-micelle and viscoelastic continuum behaviors (see Section 5.2). However, in the frequency range (typically > 10 MHz) where the cooperative modes are unimportant, quadrupolar relaxation of counterion and surfactant nuclei can yield useful, albeit somewhat model-dependent, information about micelle size and nematic order.^{37,39}

4.6 Cubic Phases

According to the topology of their microstructure, amphiphilic cubic phases are either of the micellar type with a three-dimensional periodic arrangement of nonspherical surfactant aggregates, or of the bicontinuous type with both aqueous and nonpolar regions connected over macroscopic distances in all three dimensions.⁵ In both types of cubic phase, surface diffusion is the major relaxation process. For micellar cubic phases, the spectral densities can be calculated as for nematic phases, also including molecular exchange between differently oriented micelles.⁴⁰

The microstructure of bicontinuous cubic phases is usually modeled in terms of certain triply periodic minimal surfaces. Due to the high symmetry of these surfaces, the surface-diffusion spectral densities should be nearly Lorentzian (as for diffusion on a sphere). The effective correlation times can then be expressed as⁴¹

$$\tau_s = -\frac{1 - cQ}{6D_s\langle K \rangle} \quad (9)$$

with c a numerical constant, Q the fourth-rank cubic order parameter, and $\langle K \rangle$ the (negative) average Gaussian curvature of the minimal surface, related via the Gauss–Bonnet theorem to the unit cell surface area and topology (Euler–Poincaré characteristic). The correlation time τ_s decreases strongly with increasing topological complexity and can therefore, in contrast to X-ray diffraction, distinguish among different microstructures that belong to the same crystallographic space group.⁴¹

The quadrupolar relaxation dispersion of surfactant chain and headgroup nuclei has been used to determine micelle dimensions in cubic phases.^{42,43} Since only powder samples of cubic phases have been studied so far,^{25,42,43} the full model-independent information content of the relaxation has not been extracted. Although sometimes referred to as the ‘viscous isotropic phase’, the cubic phase has an inherently anisotropic relaxation behavior (see Section 2.4) and the two irreducible CFSDs can be determined from single crystal relaxation data.⁴⁰

4.7 Low-Symmetry Phases

Although attractive with regard to their rich model-independent information content (see Table 2), amphiphilic phases of lower than hexagonal symmetry have not yet been subjected to spin relaxation studies. The four irreducible CFSDs from triply periodic tetragonal and rhombohedral phases might be analyzed in terms of surface diffusion on minimal surfaces, as for bicontinuous cubic phases. For two-dimensional rectangular phases, the ribbon-frame spectral densities discussed in Section 4.4 should be appropriate. Biaxial nematic phases pose a greater challenge however, in view of the large number of model parameters needed to describe surface diffusion on biaxial micelles undergoing asymmetric-top reorientation in a biaxial potential of mean torque.

5 LONG-WAVELENGTH DIRECTOR FLUCTUATIONS

5.1 General Considerations

For noncubic phases, spin relaxation in the sub-MHz frequency range is usually dominated by slow director fluctuations. The actual dynamic process inducing spin relaxation can be either long-range molecular diffusion or the intrinsic dynamics of collective modes. The theory of spin relaxation due to such processes is based on a phenomenological continuum description of liquid crystal mechanics, carried to second order in the elastic deformations.⁴⁴ The relaxation theory has so far been developed only for the uniaxial nematic and lamellar phases. Information about long-wavelength director fluctuations is contained in the anisotropic, secular LFSD $J_{00}^L(0; \beta)$ and in the low-frequency relaxation dispersion accessible by field cycling, echo train, and spin lock techniques (see Section 2.5).

5.2 Uniaxial Nematic Phases

The orientational state of a uniaxial nematic phase is specified at the continuum level by the director field $\mathbf{n}(\mathbf{r})$, where $\mathbf{n}$ is the unit vector along the principal axis of the micelle ordering tensor averaged over a macroscopically small volume of order λ_c^3 around the point $\mathbf{r}$. The three CFSDs involve time correlation functions of the transverse director components $\mathbf{n}_\perp = (n_x, n_y)$, which measure the orientational deviation of the director from the symmetry axis of the phase.

The CFSD $J_{11}^C(\omega_0)$, which is of second order in $n_\perp$, has a complicated dispersion with three regimes (equations (10a)–(10c)):

$$J_{11}^C(\omega_0) = \alpha_N \frac{\xi_m}{D_e} \left[1 - \left(\frac{\omega_0}{2\omega_m} \right)^{1/2} \right], \quad \omega_0 \ll \omega_m \quad (10a)$$

$$J_{11}^C(\omega_0) = \frac{\alpha_N}{(2D_e\omega_0)^{1/2}}, \quad \omega_m \ll \omega_0 \ll \omega_c \quad (10b)$$

$$J_{11}^C(\omega_0) = \alpha_N \frac{(4\pi)^2 D_e}{\lambda_c^3 \omega_0^2}, \quad \omega_c \ll \omega_0 \quad (10c)$$

with $\alpha_N = \frac{3}{4}\pi \langle \chi \rangle^2 k_B T / K$, $D_e = D + K/\eta$, K and η the effective curvature-elasticity and viscosity of the nematic fluid,⁴⁴ and D the long-range diffusion coefficient of the spin-bearing species. Further, $\omega_c = D_e (2\pi/\lambda_c)^2$ and $\omega_m = D_e/\xi_m^2$, with $\xi_m = \sqrt{\mu_0 K \Delta \chi} / B_0$ the magnetic coherence length.⁴⁴ Since, in amphiphilic nematic phases, $\omega_c/2\pi$ is typically of order 1 MHz, the classical⁴⁵ $1/\sqrt{\omega_0}$ dispersion regime in equation (10b) is accessible only with special techniques such as field cycling. In the conventional MHz range, only the high-frequency $1/\omega_0^2$ tail contributes to the relaxation (at < 10 MHz). In this frequency range, however, the theory may be inaccurate since short-wavelength (of order λ_c) continuum modes and single-micelle restricted tumbling modes make comparable contributions.

In the presence of a magnetic field, a stationary nematic sample (of thickness $\gg \xi_m$) adopts either a parallel or a perpendicular phase orientation with respect to the field. According to equation (5), the secular LFSD then involves only the CFSDs $J_{00}^C(0)$ and $J_{22}^C(0)$. Since these are of fourth order in $n_\perp$, the rates of molecular diffusion (D) and viscoelastic mode relaxation (K/η) are no longer additive.⁴⁶ For the case $D \gg K/\eta$ which usually applies to counterions, the result is⁴⁶

$$J_{00}^C(0) = 3J_{22}^C(0) = \langle \chi \rangle^2 \left(\frac{3k_B T}{4\pi K} \right)^2 \frac{1}{D} [\ln(2\pi \xi_m/\lambda_c) - 1.119] \quad (11)$$

The secular LFSD can thus be used to determine either the curvature-elasticity K or the long-range diffusion coefficient D .⁴⁶

The second-order adiabatic CFSD $J_{11}^C(0)$ in equation (10) can be obtained from relaxation studies at oblique phase orientations, achievable by sample spinning techniques. Two complications then arise. First, the magnetic field breaks the intrinsic uniaxial symmetry of the nematic phase, thus altering the low-frequency ($\omega_0 < \omega_m$) relaxation behavior.⁴⁷ Due to the orientation-dependent magnetic quenching of long-wavelength elastic fluctuation modes, the relaxation anisotropy involves CFSDs $J_{np}^C(0)$ with $n \neq p$, and hence no longer obeys equation (5).⁴⁷ (equation (10a) and equation (11) are strictly valid only for parallel alignment.) Second, since $J_{11}^C(0)$ exceeds $J_{00}^C(0)$ by a factor $\xi_m K/k_B T$ of order 10^3 , the conventional perturbation theory of spin relaxation may break down.

5.3 Lamellar Phases

Due to its layered microstructure, the lamellar phase differs fundamentally from a nematic fluid in its mechanical properties. Since the orientation of the bilayer normal (the director) is coupled to the position of the bilayer, director fluctuations in lamellar phases are suppressed not only by the bending rigidity of the bilayers but also by the (osmotic) forces that maintain the bilayer spacing. The continuum-mechanical description of the lamellar phase thus involves two elastic constants:⁴⁴ the splay-curvature modulus K_1 and the osmotic compression modulus $\bar{B}$. These are related to the average bilayer spacing d , the bilayer bending rigidity κ , and the curvature $V''(d)$ of the bilayer interaction as: $K_1 = \kappa/d$ and $\bar{B} = d V''(d)$. The lateral orientational correlation length $\xi_p = (d^2 K_1/\bar{B})^{1/4}$, also called the patch length, defines the crossover from a short-wavelength regime with independent bilayer fluctuations to a long-wavelength regime with highly coupled bilayer fluctuations. Since interbilayer forces limit the amplitude of long-wavelength fluctuation modes, magnetic quenching is unimportant in lamellar phases.

As in the nematic case, the dispersion of the second-order CFSD $J_{11}^C(\omega_0)$ exhibits three regimes (equations (12a)–(12c)):⁴⁸

$$J_{11}^C(\omega_0) = \alpha_L \frac{\xi_p^2}{D_e} \left[\ln \left(\frac{d}{L_z} + \frac{\omega_0}{\omega_p} \right)^{-1} + \frac{\omega_0}{\omega_p} \right], \quad \omega_0 \ll \omega_p \quad (12a)$$

$$J_{11}^C(\omega_0) = \alpha_L \frac{\pi}{\omega_0}, \quad \omega_p \ll \omega_0 \ll \omega_a \quad (12b)$$

$$J_{11}^C(\omega_0) = \alpha_L \frac{2\pi^2 D_e}{a^2 \omega_0^2}, \quad \omega_a \ll \omega_0 \quad (12c)$$

with $\alpha_L = (3/16\pi) \langle \chi \rangle^2 k_B T / \kappa$, $D_e = D_\perp + K_1/\eta$, $\omega_a = D_e(\pi/a)^2$, and $\omega_p = D_e \pi / \xi_p^2$. Further, L_z is the sample thickness and a is a lateral cut-off length, with a^2 of the order of the surfactant cross-section.

The adiabatic CFSD $J_{11}^C(0)$ is proportional to $\langle u^2 \rangle$, with u the vertical bilayer displacement, and hence exhibits a logarithmic divergence with sample size, characteristic of one-dimensional crystals.⁴⁴ At frequencies $\omega_0 \gg \omega_p$, $J_{11}^C(\omega_0)$ reflects independent bilayer fluctuations and the range $\omega_p \ll \omega_0 \ll \omega_a$ corresponds to the classical $1/\omega_0$ dispersion regime,⁴⁹ where $J_{11}^C(\omega_0)$ depends neither on the inter-bilayer forces (ξ_p) nor on the fluctuation rate (D_e). Since ξ_p is generally of the same order as the bilayer spacing d , $\omega_p/2\pi$ is of order 10 MHz for typical lamellar phases (but lower for very dilute samples). The experimentally accessible low-frequency dispersion (see Section 2.5) then reflects coupled bilayer fluctuations and can thus, like the adiabatic CFSD $J_{11}^C(0)$, provide information about inter-bilayer forces.

1 INTRODUCTION

Solid-state NMR provides some of the most powerful techniques for elucidating details of segmental dynamics in solid materials.¹ Such dynamics have important effects on mechanical and conduction properties of polymers, activity of proteins, stability of pharmaceuticals, transport properties in zeolites, and behavior of amorphous materials near the glass transition.^{2–7} While fast dynamics can be characterized to some extent by NMR lineshape analysis and relaxation-time measurements can characterize correlation times over a wide range (see also **Ultraslow Motions in Solids**, Volume 8), the most specific information is obtained in exchange NMR experiments, where relatively slow segmental reorientations with rates of $0.1\text{--}10\,000\text{ s}^{-1}$ are observed in terms of changes of orientation-dependent NMR frequencies.^{1,8–11} Correlation times and their distributions, reorientation-angle distributions, orientational memory, rate memory, the existence of dynamic heterogeneities, and their size can be characterized by 1D, 2D, 3D, and reduced 4D exchange NMR (see **Polymer Dynamics & Order from Multidimensional Solid State NMR**, Volume 6).^{1,12–20} However, the sensitivity and resolution of these traditional exchange-NMR techniques have been limited, since anisotropy-broadened lineshapes or strong sidebands in

magic-angle spinning spectra were required. Only by specific isotopic labeling could these limitations be eliminated in part.

The centerband-only detection of exchange (CODEX) NMR technique has overcome these problems, making it possible to observe and characterize slow ($k = 0.1\text{ s}^{-1}$ to 3000 s^{-1}) segmental reorientations with the highest available NMR sensitivity and site resolution, in sideband-free magic-angle spinning spectra.^{21,22} From short series of one-dimensional macroscopic rotation of the sample (MAS) spectra, the correlation function and correlation time can be determined, and it can be established whether the motion is diffusive or whether it involves jumps between discrete sites, whose number can be measured precisely if all segments are mobile. In addition, motional amplitudes can be estimated, with relatively high sensitivity to small-angle motions. This information is obtained for each site with a resolved line in the sideband-free MAS spectrum.

2 EXCHANGE NMR UNDER MAS, AND ROTOR SYNCHRONIZATION

Figure 1(a) shows the principle of stimulated-echo and exchange-NMR experiments, of which CODEX is an example.^{13,16,23–26} After evolution of transverse magnetization during a time t_1 , one component of the magnetization is stored along the z-direction during the long mixing time t_m . After a 90° read-out pulse, a stimulated echo forms at $t_2 = t_1$ for segments that did not change frequency during t_m . A pure stimulated echo is obtained by storing the two orthogonal components of the magnetization before t_m in alternate transients and combining their signals after read-out pulses of suitable phase (see Figure 1(a)). In a 2D exchange experiment, the time signal during the period t_2 is observed, and the t_1 period is incremented systematically.

The first exchange NMR experiments to measure reorientations under MAS were performed by Kentgens et al.²⁷ Their crucial innovation was the introduction of ‘rotor synchronization’ of the pulse sequence, i.e., making sure that t_m is an integer number of rotation periods, so that the precession of the magnetization resumes at the same rotor orientation where it stopped at the beginning of the mixing time. Otherwise, reorientations of segments relative to the external field occur due to the MAS and overwhelm the more subtle effects of intrinsic segmental reorientations. In later experiments, synchronization with the beginning of the evolution period was also used, in order to achieve pure-phase 2D MAS exchange spectra.²⁸ Recently introduced one-dimensional versions of the sideband-exchange experiment use similar rotor synchronization.^{29,30}

Rotor synchronization for short mixing times can be achieved simply by precise timing of the mixing time. However, for long mixing times, this is not sufficient. For instance, a $\pm 1\text{-Hz}$ deviation from the rotation rate results in a $\pm 36^\circ$ deviation in the rotor phase after 100 ms, and complete uncertainty of the rotor phase after $t_m = 1\text{ s}$. Therefore, trigger-based active rotor synchronization is necessary. The optical signal of the spinning-speed detector, usually made discrete into ‘high’ and ‘low’ states by a Schmitt trigger, is used to start the pulse sequence at a certain rotor orientation, namely at the transition from high to low or low to high. Based on the trigger, one can resume pulsing at the same rotor orientation tens or hundreds of rotations later. In practice, triggering during a pulse such

Figure 1 (a) Basic stimulated-echo and exchange-NMR pulse sequence. The fundamental time signals that produce the stimulated echo are indicated. Pointed brackets indicate powder averaging. Cosine and sine components measured with the indicated pulse phases are added in subsequent transients. (b) Basic CODEX pulse sequence and its synchronization with the sample rotation. 90° pulses are shown filled. The series of 180° pulses (short open boxes) during t_1 and t_2 recouple the anisotropic chemical shift, while removing the isotropic shift. The xy-8 phase sequence is used for the 180° -pulse trains. Note the change in the phase of the read-out pulse for the sine-component (+y in (a), -y here); it is required to achieve the correct chemical-shift recoupling. (c) Pulse sequence for obtaining the reference signal S_0 , produced by interchanging t_m and t_z in the sequence (b)

as cross polarization should be avoided – in case the trigger signal is absent, the pulse would last indefinitely. To ensure the same rotor orientation at the beginning and end of t_m , the (relatively short) time period between the trigger signal and the start of t_m is reproduced after a trigger signal near the end of t_m . This is indicated by the bold arrows at the bottom of Figure 1(b). Consistent triggering requires the trigger mark on the rotor to be sharp; in practice, a straight pen mark is found to be sufficient.

3 EXPLANATION OF THE CODEX PULSE SEQUENCE

Simply put, CODEX is a stimulated-echo experiment under MAS conditions, with chemical-shift-anisotropy recoupling and intensity referencing in the tradition of REDOR.³¹ Figure 1(b) shows the CODEX pulse sequence. After cross-polarization (or single-pulse excitation), the magnetization evolves under the anisotropic chemical shift, recoupled by a series of 180° pulses spaced by $t_r/2$.^{22,32} Then, one component of the magnetization is stored for the mixing time t_m , during which motion can occur. The mixing time is a multiple of the rotation period t_r . In successive transients, the phases of the 90° -pulses that bracket the mixing time are changed together by 90° , so that both components, $\cos \Phi_1$ and $\sin \Phi_1$, of the magnetization are retained alternately. If the storage pulse and the read-out pulse always have opposite signs, the sum of two transients yields $\cos \Phi_1 + i \sin \Phi_1$. Except for a scaling factor of 0.5, the signal is effectively the same as if no 90° -pulses

and mixing time had been applied, and a rotor echo forms at the end of the second recoupling period ($t_2 = t_1$).

The total phase $\Phi_1 + \Phi_2 = |\Phi_2| - |\Phi_1|$ of the magnetization at the end of the second recoupling period of duration $N/2 t_r$ is obtained from

$$\Phi_1 = \frac{N}{2} \left(- \int_0^{t_r/2} \omega_1(t) dt + \int_{t_r/2}^{t_r} \omega_1(t) dt \right) = -N \int_0^{t_r/2} \omega_1(t) dt \quad (1a)$$

$$\Phi_2 = \frac{N}{2} \left(\int_0^{t_r/2} \omega_2(t) dt - \int_{t_r/2}^{t_r} \omega_2(t) dt \right) = N \int_0^{t_r/2} \omega_2(t) dt \quad (1b)$$

with the frequencies $\omega_1(t)$ and $\omega_2(t)$ before and after t_m , respectively.²² In the second step of equation (1a), a standard result of recoupling of inhomogeneous NMR interactions (e.g., chemical shift anisotropy or spin-pair dipolar couplings) was used.^{31,32} If $\omega_1(t) = \omega_2(t)$, i.e., if no exchange occurs, equation (1) leads to $\Phi_1 + \Phi_2 = |\Phi_2| - |\Phi_1| = 0$; in other words, the magnetization is refocused in a stimulated echo along its original direction.

At the end of the second recoupling period, the total magnetization is along the original direction that it had during CP. The full magnetization is stored along the z-axis during the period t_z , and subsequently read out for detection. To suppress spinning sidebands during detection, the total suppression of sidebands (TOSS) sequence can be used before detection.³³ Since motion-induced dephasing can break the cylindrical symmetry around the rotor axis required for TOSS, the duration of t_z is incremented in K steps over a full rotation period.¹ This ensures that TOSS suppresses all sidebands except for orders nK (for details see deAzevedo et al.).²²

In a simple CODEX experiment, the signal intensity $S(t_m, \delta N t_r)$ is observed; here we have normalized the time $N t_r$ with the chemical-shift anisotropy parameter δ .¹ To remove effects of T_1 relaxation during t_m and of T_2 relaxation during $N t_r$, a reference spectrum $S_0 = S(0, \delta N t_r)$ is required that has all the same relaxation factors but no motion during t_m . This is achieved by simply interchanging the durations of t_m and t_z , see Figure 1(c). More generally, the requirement is that in the reference experiment t_m is sufficiently short ($t_m = t_r < 1$ ms) while the sum $t_m + t_z$ is the same as in the actual CODEX spectrum. In practice, effects of spectrometer drift are minimized by alternating measurements between CODEX signal S and reference signal S_0 approximately every five minutes. The ratio $S(t_m, \delta N t_r)/S(0, \delta N t_r)$ can be plotted as a function of t_m or $\delta N t_r$, to characterize the correlation function or the motional geometry, respectively.

Often, it is advantageous to subtract the CODEX spectrum $S = S(t_m, \delta N t_r)$ from the reference spectrum $S_0 = S(0, \delta N t_r)$, to obtain a pure-exchange CODEX spectrum $\Delta S = S_0 - S$. In this difference spectrum, the signals of non-exchanging components are removed from the spectrum. Figure 2(a) shows an example of this procedure for glassy poly(methyl methacrylate), PMMA, measured near ambient temperature. In Figure 2(b), a series of pure-exchange CODEX spectra of PMMA are plotted as a function of the mixing time; they show that some of the sidegroups of this polymer are undergoing large-amplitude motions in the glassy state.^{17,34}

The pure-exchange approach can also serve as a useful ‘filter’ for the signals of slowly-moving groups in a multi-component system.

The normalized pure-exchange CODEX intensity is given by

$$E(t_m, \delta N t_r) = \frac{\Delta S(t_m, \delta N t_r)}{S(0, \delta N t_r)} = \frac{S(0, \delta N t_r) - S(t_m, \delta N t_r)}{S(0, \delta N t_r)} \quad (2)$$

The nomenclature was chosen in analogy to REDOR, where the normalized dephasing provides information on internuclear distances.^{31,22}

The t_m -dependence of the pure-exchange CODEX intensity for PMMA and two crystalline model compounds, dimethyl sulfone (DMS) and methylmalonic acid, is plotted in Figure 3(a). The resulting curves correspond to the correlation functions of these dynamics on the millisecond time scale. For DMS, a single-exponential curve is obtained, while PMMA shows some non-exponentiality. Methylmalonic acid shows no exchange except for ^{13}C spin diffusion (see Section 5.1). In Figure 3(b), exchange due to helical jumps in the crystallites of isotactic polypropylene is shown.^{28,21}

4 ANALYSIS AND SIMULATION OF CODEX CURVES

4.1 Reorientation-Angle Analysis Based on the Difference Tensor

CODEX can give more information than just the correlation function obtained by recording the intensity as a function of t_m . Through variation of the duration $N t_r$ of the evolution under the recoupled CSA, the amplitude of the reorientations during t_m can be determined. The nuclear spins evolve for $N/2$ rotor periods with the phase Φ_1 before t_m , and for $N/2$ rotor periods with the corresponding phase Φ_2 after t_m . The dephasing factor

Figure 2 (a) Full reference spectrum S_0 , spectrum S after CODEX dephasing and pure-exchange CODEX spectrum $\Delta S = S_0 - S$ of unlabeled PMMA at 300 K, for $t_m = 500$ ms and $N t_r = 800$ μ s. The intensity of ΔS is low since only a minority of the sidegroups (35%) are undergoing flips. (b) Series of pure-exchange CODEX spectra of PMMA at 300 K, $\nu_r = 6.5$ kHz, and $N t_r = 615$ μ s, as a function of t_m as indicated. For the COO carbon, $\delta N t_r = 8\pi$; for the OCH₃ group, $\delta N t_r = 3.8\pi$. Large-amplitude side-group and smaller-amplitude backbone motions are observed

Figure 3 Correlation functions of slow segmental motions obtained from the normalized pure-exchange CODEX intensities $\Delta S/S_0 = E(t_m, \delta N t_r)$ as a function of t_m for (a) COO groups in methylmalonic acid ($T = 300$ K, $\delta N t_r = 7.6\pi$); COO groups in PMMA ($T = 288$ K, $\delta N t_r = 8\pi$); CH_3 groups in DMS ($T = 288$ K, $\delta N t_r = 12.4\pi$); and (b) CH and CH_2 groups in iPP ($T = 365$ K; $\delta N t_r = 3.6\pi$ and 8.5π , respectively). On the right, the expected final intensity values for M-site jumps are marked

modulating the amplitude of the signal component detected in the CODEX MAS signal is therefore

$$\frac{S(t_m, \delta N t_r)}{S(0, \delta N t_r)} = \text{Re}(\exp(i(\Phi_1 + \Phi_2))) = \langle \cos(|\Phi_2| - |\Phi_1|) \rangle$$

$$= \left\langle \cos \left(N \int_0^{t_r/2} (\omega_2(t) - \omega_1(t)) dt \right) \right\rangle \quad (3)$$

The pointed brackets indicate the powder average, which also contains the effect of the correlation time τ_c and mixing time t_m . Note that according to equations (2) and (3), the pure-exchange signal is related directly to the dephasing factor, $E(t_m, \delta N t_r) = 1 - S(t_m, \delta N t_r)/S_0$. In equation (3), the phase $|\Phi_2| - |\Phi_1|$, which depends on $\delta N t_r$ and the reorientation angles ($\alpha_R, \beta_R, \gamma_R$), can be considered as the phase acquired within a time of $N/2 t_r$ under the action of the chemical-shift difference tensor

$$\vec{\sigma}^\Delta = (\vec{\sigma}_2 - \vec{\sigma}_1) \quad (4a)$$

since

$$\omega_2 - \omega_1 = -\gamma B_0 \frac{\vec{B}_0^T}{B_0} (\vec{\sigma}_2 - \vec{\sigma}_1) \frac{\vec{B}_0}{B_0} \quad (4b)$$

The ‘width’ (principal-value range) $\gamma B_0 N |\sigma_{33}^\Delta - \sigma_{11}^\Delta|$ of the scaled chemical-shift difference tensor $\gamma B_0 N \vec{\sigma}^\Delta$ relative to the spinning speed ω_r determines whether there is significant dephasing due to the anisotropy, i.e., whether the experiment is sensitive to the segmental reorientation. By increasing the number of rotor cycles N , we can enhance the anisotropy to large values $\gamma B_0 N |\sigma_{33}^\Delta - \sigma_{11}^\Delta| \gg \omega_r$. The useful role of the difference tensor in CODEX simulations will be discussed in Section 4.3 below.

Uniaxial interactions, i.e., with $\eta = 0$, are particularly convenient to treat analytically, because only the unique principal axis needs to be considered. This case is also quite commonly found, e.g., for dipolar couplings in a spin pair or for the ^2H quadrupolar coupling. Therefore, it is instructive to calculate the difference tensor analytically for $\eta = 0$. Due

to the uniaxiality, the reorientation is fully characterized by a single reorientation angle β_R between the unique principal axis before and after the mixing time. In the specific case of $\eta = 0$, the principal values of the difference tensor are $\sigma_{22}^\Delta = 0$ and the full-width anisotropy $|\sigma_{33}^\Delta - \sigma_{11}^\Delta|$ of the difference tensor, i.e., the range of possible frequency differences, is^{22,35}

$$|\sigma_{33}^\Delta - \sigma_{11}^\Delta| = |(\sigma_{33} - \sigma_{11}) 2 \sin \beta_R| \quad (5)$$

This represents a strong linear dependence on the reorientation angle for $\beta_R < 45^\circ$, which permits relatively easy detection of small-angle motions. It compares favorably with the more common $(3 \cos^2 \beta_R - 1)/2$ angle dependence, which is insensitive to β_R for $\beta_R < 15^\circ$.

Figure 4(a) shows simulated pure-exchange CODEX curves as a function of $\delta N t_r$ for different reorientation angles β_R . The predicted sensitivity to small-angle motions is clearly recognizable. Experimental data points for DMS are also shown. In Figure 4(b), the pure-exchange CODEX intensity $E(\delta N t_r)$ for helical jumps in the crystallites of isotactic polypropylene (iPP) at 365 K and for backbone motion in glassy PMMA at 293 K are shown.^{21,28,36} Based on the unitless variable $\delta N t_r$, the motion of iPP is immediately recognized as being of large amplitude, while the methylene groups in the backbone of PMMA reorient by approximately 10° .²²

For a non-uniaxial interaction, the reorientation of a principal-axes system must be described in terms of three transformation coordinates. As already indicated above, these are usually chosen as the Euler angles $\alpha_R, \beta_R, \gamma_R$ between the initial and final PAS orientations. As in the case of $\eta = 0$, calculations of the width of the difference tensor $|\omega_{33}^\Delta - \omega_{11}^\Delta|$ for general values of η show an initial linear dependence on the reorientation angles β_R and $\varepsilon_R = \alpha_R + \gamma_R$. This can be generally proved by calculating the eigenvalues of the difference tensor for small values of β_R and ε_R .²²

A simple result is also found for the case of a rotation by an angle β'_R around the n 'th principal axis of the interaction tensor $\vec{\sigma}$. Here, $\sigma_{22}^\Delta = 0$ and

$$|\sigma_{33}^\Delta - \sigma_{11}^\Delta| = |(\sigma_{kk} - \sigma_{mm}) 2 \sin \beta'_R| \quad (6)$$

Figure 4 Measurement of the motional amplitude by recording normalized pure-exchange CODEX intensities $\Delta S/S_0 = E(t_m, \delta N t_r)$ as a function of $\delta N t_r$. (a) DMS at 288 K, $t_m = 75$ ms, and $\nu_r = 5.5$ kHz. Also shown are simulations, for $\eta = 0$, of reorientations of the unique principal axis by 10° or 170°, 20° or 160°, 30° or 150°, 50° or 130°, and 70° to 110° (curves in this large-amplitude range are virtually indistinguishable). (b) CODEX intensities $E(t_m, \delta N t_r)$ as a function of $\delta N t_r$ for isotactic polypropylene (iPP) at 365 K, $t_m = 1$ s, and for the backbone of glassy PMMA at 293 K, $t_m = 0.5$ s. Comparison with (a) immediately shows that the motions in iPP are of large amplitude, while those of the PMMA backbone are restricted

where n , k , and m label the three principal axes of $\vec{\sigma}$. This is completely analogous to equation (5).

The quantitative analysis of CODEX data requires knowledge of three principal values of the chemical shift tensor, or at least of the chemical-shift anisotropy parameter δ . These values can be obtained in a variety of ways. A first estimate can be obtained based on the tabulated CSA principal values of similar chemical groups.³⁷ Various methods of experimental CSA measurements have been described in the literature.^{38–40} The estimation of $|\delta|$ by CSA recoupling under MAS very similar to CODEX has been demonstrated by deAzevedo et al.²²

In a view traditionally taken in REDOR, rather than considering N as scaling the difference tensor relative to the spinning speed, it is considered that $N t_r$ is the total time of evolution under the influence of the anisotropic interaction.³² Then it is found that the dephasing is independent of the spinning speed and only depends on the total time $N t_r$.²² Due to this ω_r -independence, the CODEX pulse sequence works up to very high spinning speeds.

4.2 The Role of the Reorientation-Angle Distribution

In the case of a uniaxial NMR interaction, i.e., $\eta = 0$, the information content of an exchange experiment at a given mixing time t_m can be summarized in terms of the reorientation-angle distribution $R(\beta_R, t_m/\tau_c)$, i.e., the probability density of finding a reorientation angle β_R after a mixing time t_m .^{1,14,16,41} Since the correlation time τ_c is the natural reference for t_m , only their ratio, t_m/τ_c , is relevant for the reorientation-angle distribution. The dephasing or pure-exchange intensity CODEX curves are simply $R(\beta_R, t_m/\tau_c)$ -weighted superpositions of the CODEX curves $\varepsilon(\delta N t_r; \beta_R)$ for specific β_R

values.^{16,42}

$$E(t_m, \delta N t_r) = \int_0^{90^\circ} R\left(\beta_R, \frac{t_m}{\tau_c}\right) \varepsilon(\delta N t_r; \beta_R) d\beta_R \quad (7)$$

The integration weighting by $\sin \beta_R$ is contained in $R(\beta_R, t_m/\tau_c)$. The calculation of $\varepsilon(\delta N t_r; \beta_R)$ is outlined in equation (10) below. Note that while all $\varepsilon(\delta N t_r; \beta_R)$ have the same shape except for the $\sin \beta_R$ – scaling of their x-axes, their superposition $E(t_m, \delta N t_r)$ in general has a different shape (to visualize this, consider that similarly the sum of Gaussian bell curves of different widths, even when they have the same center, is not a Gaussian). For a few motional models, the reorientation-angle distributions $R(\beta_R, t_m/\tau_c)$ and corresponding $E(\delta N t_r; t_m)$ curves are shown in Figure 6. They will be discussed in more detail below.

For non-uniaxial interactions, β_R in this discussion and in equation (7) should be replaced with the full set of reorientation angles $(\alpha_R, \beta_R, \gamma_R)$. For specific motions, other angular variables may be more convenient. For rotations around a given axis, such as the helix axis in helical jumps or the invariant axis in uniaxial rotational diffusion, the angle ψ of rotation around that axis is most convenient.

4.3 Simulation Procedure

For simulations of CODEX curves, each subcurve $\varepsilon(\delta N t_r; \alpha_R, \beta_R, \gamma_R)$ needed for equation (7) is calculated based on equation (3), using the following steps:

- (i) Choose a convenient frame to rotate $\vec{\sigma}_1$ to $\vec{\sigma}_2$. In this frame, $\vec{\sigma}_1$ is expressed by a 3×3 matrix, and the rotation can be performed using Cartesian rotation matrices,

$$\vec{\sigma}_2 = \vec{R}(\alpha_R, \beta_R, \gamma_R) \vec{\sigma}_1 \vec{R}^T(\alpha_R, \beta_R, \gamma_R) \quad (8)$$

or, alternatively, Wigner rotation matrices. The rotation is defined by the Euler angles $\alpha_R, \beta_R, \gamma_R$ or by other angles specifying the motion that the segment is supposed to undergo (e.g., the rotation angle around a given axis).

- (ii) Calculate the difference tensor (3×3 matrix) $\vec{\sigma}^\Delta = (\vec{\sigma}_2 - \vec{\sigma}_1)$.
- (iii) Determine the principal values of $\vec{\sigma}^\Delta$ (i.e., diagonalize $\vec{\sigma}^\Delta$). Calculate its anisotropy parameter δ_Δ and asymmetry parameter η_Δ .
- (iv) We can evaluate the integral in equation (3) as follows,

$$\begin{aligned} \int_0^{t_r/2} (\omega_2(t) - \omega_1(t)) dt &= \int_0^{t_r/2} \omega^\Delta(t) dt \\ &= \tilde{S}_1(\delta_\Delta, \eta_\Delta, \alpha_\Delta, \beta_\Delta, \gamma_\Delta) \frac{t_r}{2} \\ &= \delta_\Delta \sqrt{2} \left\{ \frac{1}{3} \eta_\Delta \sin 2\alpha_\Delta \sin \beta_\Delta \cos \gamma_\Delta \right. \\ &\quad \left. + \frac{1}{2} \sin 2\beta_\Delta \left(1 + \frac{1}{3} \eta_\Delta \cos 2\alpha_\Delta \right) \right. \\ &\quad \left. \times \sin \gamma_\Delta \right\} \frac{t_r}{2} \end{aligned} \quad (9)$$

using the Euler angles $\alpha_\Delta, \beta_\Delta, \gamma_\Delta$ that specify the orientation of the principal-axes system of the difference

tensor in the rotor-fixed frame. The subcurve $\varepsilon(\delta N t_r; \alpha_R, \beta_R, \gamma_R)$ can now be expressed as

$$\begin{aligned} \varepsilon(\delta N t_r, \alpha_R, \beta_R, \gamma_R) &= 1 - \left\langle \cos \left(N \int_0^{t_r/2} (\omega_2(t) - \omega_1(t)) dt \right) \right\rangle \\ &= 1 - \left\langle \cos \left[\frac{\tilde{S}(\delta_\Delta, \eta_\Delta, \alpha_\Delta, \beta_\Delta, \gamma_\Delta) N t_r}{2} \right] \right\rangle_{\alpha_\Delta, \beta_\Delta, \gamma_\Delta} \end{aligned} \quad (10)$$

with $\tilde{S}(\delta_\Delta, \eta_\Delta, \alpha_\Delta, \beta_\Delta, \gamma_\Delta)$ as given in equation (9). The pointed brackets represent only the powder average over $\alpha_\Delta, \beta_\Delta, \gamma_\Delta$, i.e., the orientation of the chemical-shift difference tensor. In contrast, in equation (3) the average also included a summation over all reorientation angles. The powder average in equation (10) is calculated numerically.

- (v) Go back to (i) to repeat the calculation for a different set of reorientation angles, yielding a different CODEX subcurve.
- (vi) Obtain the CODEX curve $E(t_m, \delta N t_r)$ by superimposing the $\varepsilon(\delta N t_r; \alpha_R, \beta_R, \gamma_R)$ subcurves weighted with the reorientation angle distribution $R(\alpha_R, \beta_R, \gamma_R, t_m/\tau_c)$ for the t_m under consideration, according to equation (7).

4.4 Number of Accessible Orientations and Fraction of Mobile Segments

In complex systems such as amorphous polymers, broad distributions of correlation times and motional amplitudes often result in a complex exchange behavior. It is often a good approximation to analyze such situations in terms of a fraction f_m of significantly exchanging segments, and a component $(1 - f_m)$ that does not exchange significantly and therefore can be treated as immobile. The case of a homogeneous system in which all equivalent segments are moving similarly, as is true for most crystals, is obtained by setting $f_m = 1$.

Information about the fraction f_m and the number M of equivalent orientational sites accessible to the mobile segments is obtained from the long-time exchange intensity E_∞ . Since a fraction $1/M$ of the mobile species will reside in the originally selected site, see Figure 5, we have

$$E_\infty = E(t_m \gg \tau_c, \delta N t_r \gg 1) = f_m \left(1 - \frac{1}{M} \right) \quad (11)$$

For $f_m = 1$, the minimum E_∞ is $1/2$, obtained for $M = 2$. For diffusive reorientations of all segments, $M \gg 1$ and $E_\infty \sim 1$; note, however, that for restricted diffusion, very large phases

Figure 5 Relation between the final exchange intensity and the number of sites in an M-site jump process. At long times ($t_m \rightarrow \infty$), $1/M$ of the segments reside in the original site. Thus, the final exchange intensity E_∞ deviates from unity by $1/M$

$\delta N t_r$ will be required to reach the final state. Also, if $E_\infty < 1/2$, $f_m < 1$. In fact, equation (11), with $M = 2$ and $M \rightarrow \infty$, yields rigorous limits for f_m in terms of E_∞ :

$$E_\infty < f_m \leq 2E_\infty \quad (12)$$

From E_∞ alone, f_m and M cannot be determined unambiguously. Fortunately, the number of sites M can be measured in a four-time CODEX experiment, which is produced by concatenating two CODEX pulse sequences.²² In the first CODEX difference experiment with mixing time t_{ma} , the mobile groups are selected; then their exchange behavior, with a final value of $1/M$, is characterized selectively in another CODEX MAS section by changing the mixing time t_{mc} . Effects of T_1 relaxation decay can be eliminated by keeping the total z-period $t_{mc} + t_z$ constant. Therefore, no difference is required in the second half of the experiment. The four-time CODEX experiment has close analogies to a reduced four-dimensional (4D) exchange NMR experiment, where the orientation-dependent frequency is probed at four different times.¹⁸ The reduced 4D exchange method, and the closely related four-time exchange experiment have been used to identify the origins of the non-exponential loss of correlation above the glass-transition temperature and to estimate the size of dynamic heterogeneities.^{18–20} Four-time CODEX will make such studies much more sensitive and quantitative.

4.5 Jumps vs. Diffusive Motions

A variety of different motional models have been considered in the literature.^{1,14} They can be grouped into jump processes and diffusive motions. For instance, symmetric N-site exchange is a common jump process, while isotropic rotational diffusion is the most important example of a diffusive reorientation. Defining distinctions between pure jumps and pure diffusion are seen in the evolutions of their reorientation-angle distributions $R(\beta_R, t_m/\tau_c)$ with time t_m ; this behavior can be used in CODEX NMR to identify pure jump motions and diffusive motions. The $R(\beta_R, t_m/\tau_c)$ of four classical motional models and the corresponding CODEX curves $E(\delta N t_r, t_m)$ are shown in Figure 6.

All diffusive motions produce a characteristic change in the shape of $R(\beta_R, t_m/\tau_c)$ with increasing t_m . The sharp peak at $\beta_R = 0^\circ$ gradually broadens and approaches the wide distribution characteristic of the final stage, such as $\sin \beta_R$ for isotropic diffusion. As a result, the shape of the $E(\delta N t_r)$ CODEX curves depends strongly on t_m : For short t_m , the curves rise quite slowly because only small reorientation angles have been reached, while an earlier and faster increase in $E(\delta N t_r)$ (plotted as a function of $\delta N t_r$, with t_m only as a parameter) occurs at long t_m when larger reorientation angles have been attained. These features are clearly visible in Figures 6(c) and 6(d), where isotropic and uniaxial rotational diffusion, respectively, have been simulated.

In contrast, for many pure jump motions the only change in the reorientation-angle distribution is the relative intensity of the reorientation-angle distribution at $\beta_R = 0$ and at $\beta_R \neq 0$. This holds for all two-site jumps, circular three-site jumps, random N-site jumps, and the isotropic random-jump model. As a result, the shape of the $E(\delta N t_r, t_m)$ curves does not change

Figure 6 Time evolution of the reorientation-angle distributions $R(\beta_R, t_m/\tau_c)$ for four important motional models, and the corresponding CODEX $E(\delta Nt_r, t_m)$ curves (for a uniaxial interaction, $\eta = 0$). As indicated at the top, the line thickness decreases with increasing t_m/τ_c ($=0.1, 0.3, 1.0, 3.0$, and 10). (a) Three-site jumps, with a 109° (or equivalently 71°) jump angle. (b) Random isotropic jumps. In this model, all orientations are equally likely after the jump. (c) Isotropic rotational diffusion, without amplitude limitation. (d) Uniaxial rotational diffusion on a cone with an apex angle of 141° (or equivalently $2 \cdot 109.5^\circ$). The dashed arrows in the plots indicate the characteristic differences between the t_m/τ_c dependences for jump motions (a,b) and diffusion (c,d)

with t_m . Only its height (y-scale) increases. This is clearly visible in Figures 6(a) and (b).

Helical jumps, where sites along a helical chain are accessed sequentially, do not fall under this category, if the chain forms a 4_n helix (i.e., 4 repeat units in n turns) or more complex helix.^{1,27} Nevertheless, their change in reorientation-angle distribution is still characteristically different from that of diffusive motions. The peak at $\beta_R = 0$ does not broaden, and $R(\beta_R, t_m/\tau_c)$ consists only of a few sharp peaks whose relative height changes only slowly. The rise for short t_m will be fast and unchanged, being due to large-angle jumps between neighboring sites; only at long t_m will changes be observed due to the contribution of non-neighboring sites.

Another characteristic aspect of diffusive motions is that the number of sites M is infinite. Thus, at sufficiently large δNt_r and t_m , full exchange will be observed. This property is shared with only a very small number of pure jump processes; the isotropic random-jump model, Figure 6(b), is the only prominent example.

However, it should be noted that $M \rightarrow \infty$ is also a property of limited diffusion superimposed on jumps. Such a combined process may still be relatively difficult to distinguish from pure diffusion, in particular if the diffusion has a broad distribution of correlation times.

5 PRACTICAL CONSIDERATIONS

5.1 Spin Exchange by Dipolar Couplings

Segmental dynamics is not the only possible exchange process. Two effects based on dipolar couplings also lead to exchange of anisotropic interactions and intensity changes in the CODEX experiment. The first is relaxation-induced dipolar exchange due to dipolar couplings to heteronuclei, in particular ^{14}N and ^{15}N , that undergo significant longitudinal relaxation during t_m .^{43,44} The relaxation removes a heteronuclear coherence term from the density operator and thus reduces the stimulated echo. This effect has been described in detail by Saalwächter and Schmidt-Rohr.⁴⁴ Due to the small value of the nitrogen-carbon dipolar coupling, it is a significant problem only for CODEX experiments involving nitrogen-bonded carbon sites with small chemical-shift anisotropies. On the other hand, this relaxation-induced dipolar exchange with recoupling can be exploited to measure internuclear distances between heteronuclei.⁴⁴

The more common second effect is ^{13}C spin diffusion or spin exchange generated by homonuclear dipolar couplings and affected by the ^1H - ^{13}C dipolar coupling.^{45–48} For ^{13}C in natural abundance, it typically generates 4% exchange intensity within 0.5 s. In isotopically labeled materials, it can occur significantly within 50 ms. Apart from isotopic dilution, the only known procedure for slowing down ^{13}C spin exchange between sites with similar isotropic chemical shifts is to increase the spinning speed. Among the experiments for measuring exchange by segmental reorientation, CODEX is the only one that is compatible with high spinning speeds. We have recently shown that for unprotonated sites, an increase of the spinning speed from 8 to 28 kHz indeed decreases the spin exchange rate by a factor of 3–10.⁴⁹ Thus, CODEX under fast MAS can significantly extend the range of correlation times accessible to exchange NMR measurements.

In ^{13}C -enriched proteins, Hong et al. have circumvented the ^{13}C spin diffusion problem by performing a ^{15}N CODEX experiment followed by ^{15}N - ^{13}C transfer and ^{13}C detection.⁵⁰ The dipolar couplings between the ^{15}N nuclei, which are separated by three bonds and have smaller gyromagnetic ratios, are more than an order of magnitude reduced relative to those of ^{13}C in a uniformly labeled protein.

5.2 Accessible Range of Correlation Times

The rates for which dephasing is observed in CODEX NMR range from ~ 0.1 to $\sim 5000 \text{ s}^{-1}$. Very slow motions, which require long mixing times, can be studied better by CODEX than by any other NMR technique. The high sensitivity and good dynamic range of CODEX NMR enables detection of the $\sim 10\%$ exchange intensity that arises already within $t_m = 0.1 \tau_c$, and makes it less sensitive to signal reduction by T_1 -relaxation and the increased experiment duration when the mixing time exceeds the recycle delay. Exchange due to ^{13}C spin exchange (see above) which competes with motional exchange, is the main limitation for detecting very slow motions. Even in this aspect, CODEX is often superior. Not only can CODEX under fast MAS slow down spin diffusion among unprotonated carbons but its superior sensitivity also permits a reduction in the isotopic labeling level, or even measurements on ^{13}C in natural abundance.⁴⁹ This is

particularly relevant for systems that previously required ^{13}C enrichment for achieving sufficient sensitivity, e.g., benzene undergoing jumps and diffusion in zeolites.⁶

To understand the effect of motions on the 100- μs time scale on CODEX, consider that a clean exchange experiment requires that no motion occurs during the dephasing and rephasing periods Nt_r (i.e., $k < 1000\text{ s}^{-1}$). Nevertheless, even with frequency changes during those periods, some motional dephasing will occur. Its strong dependence on the dephasing time and near independence from the mixing time will identify its high rate.

Finally, motions with rates exceeding the chemical-shift anisotropy significantly will not be detected by CODEX, since the motionally averaged frequencies do not change during the course of the experiment. This will lead to a reduction in E_∞ , and care must be taken not to interpret these fast-moving segments as immobile. Fortunately, significant motions with rates exceeding $10\,000\text{ s}^{-1}$ can be detected by other NMR experiments.^{9–11,51,52}

5.3 Implementation of the CODEX Pulse Sequence

Due to the simplicity of the CODEX pulse sequence, the implementation of the technique is mostly straightforward. However, since the method relies on measuring signal amplitudes rather than frequency positions, some care should be taken to avoid artifacts. A fixed xy-8 phase sequence is used for the train of 180° pulses that recouple the CSA.⁵³ Effects of pulse imperfections and T_1 relaxation are minimized or eliminated using the phase cycling given by Reichert et al.⁴⁹

For protonated carbon sites, in particular CH_2 groups, the residual C–H dipolar coupling during the multiple 180° pulses leads to significant dephasing. Fortunately, this does not affect the normalized CODEX data, since the same dephasing occurs in the reference experiment. However, the intensity is degraded. The decoupling is excellent if the ^1H B_1 field strength during the ^{13}C pulses is so high that the duration of a ^{13}C 180° pulse corresponds to a $3 \times 180^\circ$ pulse length on protons.⁵⁴ In order to reduce the ^1H power required to achieve this condition, it can be advantageous to increase the duration of the ^{13}C 180° pulses, i.e., to *reduce* the ^{13}C pulse power.

6 APPLICATIONS OF CODEX

6.1 Dynamics in Complex Glassy Polymers

So far, NMR studies of slow segmental motions of unlabeled polymers in the glassy state have been virtually impossible, due to sensitivity and line-overlap problems. CODEX and its non-spinning analog, 1D PUREX, enable detailed, quantitative studies of these dynamics.²⁵ The selective observation of exchanging sites in pure-exchange CODEX and 1D PUREX spectra leads to a great increase in resolution and in the dynamic range, which in turn reduces artifacts arising from the often dominant signals of immobile sites.

Examples for the detection of flipping sidegroups in PMMA by CODEX are shown in Figures 2 and 3. The characterization of the motion as a jump process between $M = 2$ sites was confirmed in PMMA by 4-time CODEX.²² Extending these experiments to a series of glassy poly(*n*-alkyl methacrylates) with COOR sidegroups of various sizes, CODEX has revealed

that even some large cyclohexyl sidegroups can flip, but that the flipping fraction is only 9%.⁵⁵ Surprisingly, the fraction of flipping sidegroups was found to remain temperature-independent in PMMA with its small methylester sidegroup, while it increases significantly with temperature in polymers with longer sidegroups.⁵⁵ In polyphenylene dendrimers, slow dynamics in the highest-generation phenylene rings has been observed by CODEX.⁵⁶ Generally, CODEX enables us to study almost any slow dynamic process in polymers and thus learn more about the relation between chain motions and mechanical properties.

6.2 Dynamics in Peptides and Proteins

In biological systems, knowledge of the three-dimensional molecular structure is important, but further insight into the segmental dynamics is also highly valuable. Segmental mobility and function in enzymes are thought to be particularly closely related. Due to the large number of sites that may be distinguished in proteins, the sensitivity and site resolution of CODEX is indispensable for studies of slow motions. Hong and coworkers have introduced ^{13}C -detected ^{15}N CODEX for studies of slow motions in ^{13}C -labeled globular proteins.⁵⁰ In a triblock protein hydrogel, the experiments revealed large-amplitude reorientations of the α -helical segments that form the reversible cross-links.⁵⁷

7 OUTLOOK

7.1 Perspective on CODEX, PUREX, and 2D Exchange Spectra

Overall, CODEX is complementary to detailed 2D exchange NMR studies without sample rotation. The CODEX MAS approach makes it easy to identify groups with interesting dynamics, characterize their correlation times, estimate the motional amplitude, obtain information on the mobile fraction and the number of accessible sites, and identify simple jumps or more complex motions. The lineshapes of 1D PUREX spectra, which can be regarded as CODEX without sample rotation, can give valuable hints about the motional geometry.²⁵ Given enough interest, these sites can then be isotopically labeled by ^2H or ^{13}C to determine the details of the reorientation process by 2D and 3D exchange NMR; the information on the reorientation angle that is contained in 2D exchange patterns is still unparalleled, in particular for distributions of reorientation angles, and for large reorientation angles.¹

7.2 Summary

Detailed analysis of slow dynamics in complex solids is enabled by centerband-only detection of exchange (CODEX), which combines chemical-shift recoupling by 180° -pulses with exchange NMR. The analysis in terms of the chemical-shift difference tensor explains the surprising sensitivity of the experiment to small-amplitude motions. For uniaxial interactions ($\eta = 0$), this can be expressed by a simple analytical relation. The number of orientational sites accessible to the mobile segments and the fraction of mobile units are reflected in the long-time exchange intensity. Jumps and diffusive motions are distinguishable from the effect of mixing

time on the recoupling-time dependence of their exchange intensity, which reflects the characteristic changes of the reorientation-angle distributions. Pure-exchange CODEX can also be used as a dynamic filter to observe slow-moving groups selectively.

1 INTRODUCTION

Deuteron NMR spectroscopy (^2H NMR) is an extremely powerful technique for investigating molecular order and dynamics. The usefulness and uniqueness of this method lies in the wide range of timescales that are accessible for quantitative investigation. Fast molecular motion, with correlation times in the picosecond range, can be investigated by using relaxation rates to determine the orientation and temperature dependence of individual spectral density functions.¹ In the intermediate regime, processes with correlation times in the range $\tau_c \approx 10^{-4}$ – 10^{-8} s are characterized by motional narrowing effects on quadrupole echo lineshapes.² For slow motions, decay of quadrupolar order,³ selective inversion,⁴ or 2D exchange spectroscopy⁵ permit investigation of rotational dynamics with correlation times approaching the spin–lattice relaxation time, which can vary from milliseconds to several hundred seconds. This article is focused on describing ^2H NMR experiments which can be used to measure specific relaxation times, T_j , in oriented media. The primary motivation is to provide information which is essential to improving the understanding of molecular motion in thermotropic liquid crystals. Many experiments have been developed to measure different relaxation rates ($R_j = 1/T_j$); these will be summarized and their sensitivity to random and systematic errors will be considered.

The utility of ^2H NMR is enhanced by the fact that the dominant quadrupole interaction is both small enough to permit recording of undistorted spectra and sufficiently large to be a sensitive probe of local structure and dynamics. Dipolar interactions and associated many-body complications are usually negligible, and the interaction between the nuclear quadrupole moment and the local electric field gradient (EFG) tensor is described by a one-particle Hamiltonian. As a result the spin dynamics of deuterons, in realistically complicated systems, is simple enough to allow rigorous density matrix analysis of multiple pulse sequences and

relaxation behavior. This greatly facilitates the development of new NMR techniques and simplifies the interpretation of relaxation behavior, thereby providing stringent tests of theoretical descriptions of ordering and dynamics.

In discussing motion in ordered environments, it is necessary to distinguish between studies on nonmesogenic solutes dissolved in anisotropic fluids, and studies of the liquid crystal molecules themselves. Measurements of spin relaxation of small, rigid solute molecules can be interpreted without the uncertain approximations inherent in descriptions of internal motion, and provide useful tests for general theories of how an ordering potential affects the dynamic processes of small solutes. However, the weak ordering and fast motion of solutes make them unreliable probes of liquid crystal dynamics. An understanding of the basic physics of liquid crystals is better achieved through direct investigations of carefully chosen liquid crystalline materials.

In the nematic phase, the motion of liquid crystal molecules is assumed to be fast enough to be in the motional narrowing regime. Thus, the fluctuating Hamiltonian $\hat{\mathcal{H}}'(t)$ responsible for relaxation varies rapidly compared with precession under the static Hamiltonian $\hat{\mathcal{H}}_0$, i.e. the motion is fast compared with the rigid lattice linewidth. Under these circumstances, Redfield theory⁶ can be used to express the measured relaxation rates in terms of spectral densities of motion. The long-range order, which leads to a nonzero average value of the anisotropic quadrupole interaction, has profound effects on the motional spectral densities which govern spin relaxation. It is now well established that in the nematic phase, contributions to nuclear spin relaxation are made by restricted reorientation of individual molecules, internal rotations within the molecule, and by long-range quasi-coherent hydrodynamic modes such as order director fluctuations (ODFs).

In the more ordered liquid crystal phases, including smectics, lyotropics, and discotics, there is more uncertainty about the dominant motional processes. Spin relaxation studies can be used to help clarify the details of molecular dynamics in these systems. Throughout this article, Redfield theory will be used to describe the effects of molecular reorientation on spin relaxation. It should be appreciated that such motional narrowing approximations may not remain valid for these more complicated mesophases. For ultraslow motions, the concept of spectral densities is not sufficiently general to describe spin relaxation, and more rigorous approaches based on the stochastic Liouville equation must be used.

2 SPIN DYNAMICS

The time-independent Hamiltonian for a deuteron in an anisotropic environment is given by

$$\hat{\mathcal{H}}_0 = -\omega_0 \hat{I}_Z + \frac{1}{3} \omega_Q (3\hat{I}_Z^2 - \hat{\mathbf{I}} \cdot \hat{\mathbf{I}}) \quad (1)$$

Here $\omega_0 = 2\pi\nu_0$ is the Larmor frequency (in radians per second), $2\omega_Q = 4\pi\nu_Q$ is the quadrupole splitting, and $\hat{I}_Z$ is the operator for spin angular momentum about the space-fixed Z axis. Energy levels and transition frequencies associated with this Hamiltonian are illustrated in Figure 1. In isotropic liquids, where $\nu_Q = 0$, the two transitions are degenerate and occur at the Larmor frequency. In an oriented medium the quadrupolar

Figure 1 The energy level diagram for a spin-1 deuteron in a static magnetic field (left), and including the first-order quadrupolar interaction (right). Single quantum transition frequencies are indicated by vertical arrows on the diagram, and the corresponding NMR spectra are sketched

splitting between the $1 \rightarrow 2$ and $2 \rightarrow 3$ transitions ($2\nu_Q$) depends on the order parameters. Detailed discussions of the effects of orientational order on the NMR spectra of liquid crystals are available in the literature.^{7,8}

Relaxation of deuterons in an ordered medium is best described using density matrix formalism. In the Redfield limit, in the absence of rf irradiation, the spin density matrix element, $\rho_{ij}(t)$, for an ensemble of deuterons evolves according to the equation

$$\frac{\partial \rho_{ij}(t)}{\partial t} = i\omega_{ij}\rho_{ij} + \sum_{kl} R_{ijkl}[\rho_{kl}(t) - \rho_{kl}(\infty)] \quad (2)$$

Here $\omega_{ij} = (\omega_j - \omega_i)$ is the transition frequency between the eigenstates $|i\rangle$ and $|j\rangle$ of the time-independent spin Hamiltonian, the R_{ijkl} are elements of the Redfield relaxation supermatrix, and $\rho_{kl}(\infty)$ is element kl of the thermal equilibrium density matrix. There are two fundamentally different types of states of the density matrix: diagonal elements ($i = j$), which correspond to populations of the eigenstates, and coherences ($i \neq j$), which correspond to phase coherence in the wavefunctions of the eigenstates. For a single deuteron the off-diagonal density matrix elements include two single quantum coherences $\rho_{12}(t)$ and $\rho_{23}(t)$ with precession frequencies $\nu_{12} = (\Delta + \nu_Q)$ and $\nu_{23} = (\Delta - \nu_Q)$, respectively, and one double quantum coherence $\rho_{13}(t)$ with precession frequency 2Δ . In this notation, Δ is the offset from resonance. The precession frequencies of the single quantum coherences correspond to the transition frequencies illustrated in Figure 1. Diagonal density matrix elements can be used to construct two linearly independent combinations of eigenstate populations: $(\rho_{11} - \rho_{33}) = \langle \hat{I}_Z \rangle$ is the expectation value of Zeeman polarization, and $(\rho_{11} - 2\rho_{22} + \rho_{33}) = \langle \hat{Q}_Z \rangle$ is the expectation value of quadrupole order. Theoretical expressions for the relaxation behavior of the five independent density matrix elements are easy to calculate in terms of the Redfield

elements R_{ijkl} , which are in turn expressed in terms of spectral densities for molecular motion using the equations

$$R_{ijkl} = \int_0^\infty \exp[i\tau(\omega_{ik} - \omega_{jl})] \langle i | \hat{\mathcal{H}}'(t) | j \rangle \times \langle k | \hat{\mathcal{H}}'(t + \tau) | l \rangle^* d\tau \quad (3)$$

$$\hat{\mathcal{H}}'(t) = \sum_{m=-2}^2 (-1)^m A_{-m}^{(2)} \sum_{k=-2}^2 [D_{mk}^{(2)*}(t) - \langle D_{mk}^{(2)*}(0) \rangle] T_k^{(2)}(\text{PAS}) \quad (4)$$

Here the $A_{-m}^{(2)}$ are second rank spherical tensor spin operators, the $D_{mk}^{(2)}(t)$ are the time-dependent Wigner rotation matrix elements, the $T_k^{(2)}(\text{PAS})$ are spherical components of the quadrupole coupling tensor, expressed in its principal axis system (PAS), and the angular brackets $\langle \rangle$ denote an ensemble average. The $D_{mk}^{(2)}(t)$ depend on Euler angles, $\alpha(t)$, $\beta(t)$, and $\gamma(t)$, which define the time-dependent orientation of the PAS relative to a laboratory-fixed frame. The inclusion of the term $\langle D_{mk}^{(2)*}(0) \rangle$ is necessary to ensure that the relaxation Hamiltonian fluctuates about a mean value of zero, so that the Fourier transform, defined in equation (3), is convergent. In isotropic liquids the $\langle D_{mk}^{(2)*}(0) \rangle$ are zero, but in liquid crystals they define characteristic order parameters of the anisotropic phase.

Without further analysis, several implications of the theory embodied in equations (2)–(4) are apparent. First of all, since $\mathcal{H}'(t)$ gains its time dependence exclusively through orientational variables, deuteron relaxation is sensitive only to rotational motion. This implies that the spatial order characteristic of complex mesophases is not directly probed by deuteron relaxation measurements. Instead, it is necessary to rely on theories which approximate the coupling between translation and rotation. Partially for this reason, most detailed interpretations of deuteron relaxation have been confined to the nematic phase, where translational order is unimportant. Secondly, the appearance of order parameters in the fluctuating Hamiltonian leads ultimately to expressions for measurable relaxation rates which also depend on the orientational order. This implies that the spectral density functions for motion in ordered environments are fundamentally different from those for isotropic liquids. Finally, since the Redfield relaxation matrix elements depend on the average of the product of elements of $\mathcal{H}'(t)$, they include higher-rank order parameters of the form $\langle D_{mk}^{(2)*}(0) D_{mk}^{(2)*}(0) \rangle$. In principle such quantities can be derived from relaxation studies, but they do not influence the equilibrium spectra.

In oriented nematic phases the observed quadrupole splitting is proportional to $\frac{1}{2}(3 \cos^2 \beta_{\text{MP}} - 1)$, where β_{MP} is the angle between the largest component of the electric field gradient (EFG) tensor, q_{zz} , and the molecule fixed Z axis. Typically, in organic molecules, deuteron quadrupole coupling tensors have the largest component coincident with the C–D bond direction. Hence, C–D bonds which make different angles with the molecular Z axis give rise to resolved quadrupolar doublets, whose relaxation behavior can be determined independently. This provides a uniquely powerful way to investigate rotational anisotropy, but requires that the relaxation rates for each

deuteron be expressed in terms of spectral densities for the overall rotation of the molecule-fixed coordinate system. Thus, it is useful to decompose the Euler rotation from laboratory to PAS frames, Ω_{LP} , into separate transformations: a time-dependent transformation from laboratory to molecule-fixed coordinates $[\alpha_{LM}(t), \beta_{LM}(t), \gamma_{LM}(t)]$, followed by a time-independent transformation to the PAS of each individual deuterated site $(\alpha_{MP}, \beta_{MP}, \gamma_{MP})$. It can be shown¹ that there are then just three distinct spectral density functions, given by the equations

$$J_m(m\omega_0) = \frac{1}{(T_0^{(2)})^2} \sum_{k=-2}^2 \sum_{k'=-2}^2 \sum_{n=-2}^2 \sum_{n'=-2}^2 T_n^{(2)} T_{n'}^{(2)*} \quad (5)$$

$$\times D_{kn}^{(2)}(\Omega_{MP}) D_{k'n'}^{(2)*}(\Omega_{MP}) J_{mkk'}(m\omega_0)$$

where $m = 0, 1$, or 2 , and

$$T_0^{(2)} = \frac{\sqrt{6}}{4} \frac{e^2 q_{zz} Q}{\hbar} \quad (6a)$$

$$T_{\pm 1}^{(2)} = 0 \quad (6b)$$

$$T_{\pm 2}^{(2)} = \frac{\eta}{4} \frac{e^2 q_{zz} Q}{\hbar} \quad (6c)$$

Here $\eta = (q_{xx} - q_{yy})/q_{zz}$ is the asymmetry parameter of the deuteron EFG tensor. In most cases, η is small enough to ignore, and this greatly simplifies the evaluation of equation (5). Molecular motion appears in this expression through the Fourier transforms of correlation functions of time-dependent Wigner rotation matrix elements:

$$J_{mkk'}(m\omega_0) = \int_0^\infty \exp(-im\omega_0\tau) C_{mkmk'}(\tau) d\tau \quad (7a)$$

$$C_{mkmk'}(\tau) = \langle E_{mk}^{(2)*}[\Omega_{LM}(t)] E_{mk'}^{(2)}(\Omega_{LM}(t + \tau)) \rangle \quad (7b)$$

$$E_{mk}^{(2)}[\Omega_{LM}(t)] = D_{mk}^{(2)}[\Omega_{LM}(t)] - \langle D_{mk}^{(2)}[\Omega_{LM}(0)] \rangle \quad (7c)$$

In essence, the spectral densities, $J_m(m\omega_0)$ are Fourier transforms of certain correlation functions which relate the orientation of a molecule at time t to the orientation at a later time $t + \tau$. The key idea is that by the appropriate selection of relaxation experiments, the different spectral densities for individual deuterons can be determined as a function of temperature, Larmor frequency ω_0 (magnetic field strength), and orientation with respect to the static field (for sufficiently rigid mesophases). This constitutes the maximum amount of information available from deuteron relaxation experiments.

It is implicit in the formalism presented here that relaxation during rf pulses can be ignored. When this is not the case, for example in spin lock measurements in the rotating frame ($T_{1\rho}$), the same spectral densities arise but some must be evaluated at the rf field amplitude, ω_1 , rather than integer multiples of the Larmor frequency.⁹

3 EXPERIMENTAL DESIGN

Designing experiments to determine spectral densities amounts to choosing a particular state of the density matrix,

calculating its relaxation rate in terms of spectral densities, designing a rf pulse sequence that creates the desired state, and measuring the relaxation time. Pulse sequences that are currently being used to create specific population distributions or coherences are summarized in Table 1. Strategies for using combinations of experiments to determine the individual spectral densities from these measurements will be described in this section. Salient practical aspects will also be discussed: which techniques give the most reliable results and where potential problems in implementation are anticipated. To a certain extent this depends on the details of the spin system, i.e. the number and relative order of magnitude of quadrupolar splittings, and the degree of orientational order of the liquid crystal, S_{zz} and $(S_{xx} - S_{yy})$.

To date, most relaxation experiments have focused on determining $J_1(\omega_0)$ and $J_2(2\omega_0)$ from the recovery of nonequilibrium population distributions. These are the simplest, most reliable and accurate experiments. In principle, $J_1(\omega_0)$ and $J_2(2\omega_0)$ can be obtained from any two relaxation experiments which depend on linearly independent combinations of these two spectral densities. These include nonselective and selective inversion recovery measurements of Zeeman polarization, conventional (JB) and broadband (BBJB) Jeener–Broekaert excitation of quadrupole order, and two-dimensional measurements of the decay rate of double quantum coherence. In practice, the accuracy of selective inversion recovery experiments is limited because the recovery curves are biexponential. The formulae given in Table 1 refer to the initial slope of the recovery, but this is difficult to measure without introducing systematic errors. Nonselective inversion recovery with quadrupolar echo detection (IRQE) does not suffer from this disadvantage, and is the method of choice for measuring T_{1Z} . Because deuteron relaxation times in liquid crystals are short there is no need to resort to inherently less accurate methods such as saturation recovery or progressive saturation.

For studies of thermotropic liquid crystals two potentially serious instrumental problems arise. The first is temperature control: the quadrupole splitting is directly proportional to order parameters which can be strongly temperature dependent. Close to the nematic–isotropic phase transition, where the order parameter changes most rapidly, temperature coefficients as large as 5 kHz K^{-1} have been observed.¹⁰ Temperature drifts, gradients and instabilities as small as a few millidegrees can then lead to severe line broadening. Moreover, in frequency-selective preparation sequences, such as the conventional two-pulse JB sequence, a temperature drift translates into irreproducible changes in the amount of quadrupole order created. In general, accurate measurements of T_{1Z} and T_{1Q} require temperature control and gradients to less than 0.1 K , preferably to within 0.01 K . Secondly, in nematic liquid crystals, quadrupolar splittings approaching 100 kHz are common. In order to achieve uniform inversion over such large spectral widths, rf field strengths of $\nu_1 \approx 150 \text{ kHz}$ are required (typical 90° pulse lengths of $1.5\text{--}2.0 \mu\text{s}$ in a 5 mm coil). Thus, high-power amplifiers similar to those required for solid state ^2H NMR are essential. Fortunately, instrumentation with the necessary capabilities is now commercially available.

It has been shown¹¹ that the best procedure for determining $J_1(\omega_0)$ and $J_2(2\omega_0)$ is not the conventional JB experiment designed to retain both quadrupole and Zeeman order. Rather, two separate IRQE and BBJB experiments are performed which can be optimized independently for maximum

Table 1 Relaxation Experiments and Measured Spectral Densities

	Spectral Density ^a
<i>Populations</i>	
Nonselective T_{1Z} (IRQE)	
180- T^b -90 _x - τ -90 _y	$2J_1(\omega_0) + 8J_2(2\omega_0)$
Broadband T_{1Q} (BBJB)	
(90 _x -2 τ -67.5 _y -2 τ -45 _y - τ -45 _y)- T -45 _x - t -90 _x -	$6J_1(\omega_0)$
Conventional Jeener-Broekaert (JB)	
90 _x - τ -45 _y - T -45 _y	Sum: $2J_1(\omega_0) + 8J_2(2\omega_0)$ Difference: $6J_1(\omega_0)$
Selective T_{1Z}^c	
180 _x ^A - T -90 ^A	$5J_1(\omega_0) + 2J_2(2\omega_0)$
<i>Coherences</i>	
Quadrupolar echo T_{2e}	
90 _x - T -90 _y	$3J_0(0) + 3J_1(\omega_0) + 2J_2(2\omega_0)$
Multipulse quadrupolar echo T_2 (MQE)	
90 _x - τ -(90 _y -2 τ)- _n	Short τ : $3J_0(0) + 5J_1(\omega_0) + 2J_2(2\omega_0)$ Long τ : $3J_0(0) + 3J_1(\omega_0) + 2J_2(2\omega_0)$
($T = 2n\tau$)	
Selective single quantum T_2^c	
90 _x ^A - $T/2$ -180 ^A - $T/2$ -	$3J_0(0) + 3J_1(\omega_0) + 2J_2(2\omega_0)$
Double quantum T_{DQ}	
90 _x - τ -90 _x - $T/2$ -180- $T/2$ -90	$2J_1(\omega_0) + 4J_2(2\omega_0)$

^aUnits of $(3\pi^2/4)(e^2q_{zz}Q/\hbar)^2$.^b T denotes the relaxation delay.^cThe superscript A indicates that the pulse is applied selectively at the frequency of peak A.

precision and accuracy. In particular, the use of broadband (frequency-independent) procedures for exciting quadrupole order, combined with echo detection to avoid pulse recovery problems, was shown to increase greatly the accuracy with which T_{1Q} can be determined.¹¹ This is important because small uncertainties in measured values of the relaxation times propagate into larger errors in determining $J_2(2\omega_0)$.

Figure 2 illustrates the difference between conventional (JB) and broadband (BBJB) excitation of quadrupole order. The sample is pure 4-*n*-pentyl-4'-cyanobiphenyl selectively deuterated (5CB-*d*₆) in the 1,4- and 5-positions of the alkyl chain. Figure 2(a) shows the pulse sequence, spectrum, and quadrupolar order excitation profile for the conventional JB pulse pair, 90_x- τ -45_y. This sequence is inherently frequency selective, with efficiency proportional to $\sin \nu_Q \tau$. The excitation delay of $\tau = 46 \mu\text{s}$ is a particularly unfortunate choice: the spectrum shows that the sign of the quadrupole order is opposite for the C-1 and C-2 methylene deuterons and there is little excitation of quadrupole order for the methyl deuterons (C-5). It is impossible to achieve full excitation of quadrupole order for all the transitions with any single τ value. The BBJB sequence does not suffer from this limitation. Figure 2(b) shows that uniform excitation is achieved by this sequence, with total excitation time $5\tau = 46 \mu\text{s}$. Thus, for materials with several different quadrupole splittings, broadband procedures for exciting quadrupole order are definitely preferable to the simple JB pulse pair. In practice, the choice of τ in the BBJB sequence is not very critical. It is usually sufficient to use a small enough value to excite full quadrupole order for the largest splitting, and this ensures that all others will be uniformly excited. However, it must be noted that all methods of exciting quadrupole order fail as the quadrupole splitting tends to zero. For splittings less than a few kilohertz, the BBJB sequence

described here is somewhat less efficient than the simple two-pulse (JB) excitation sequence. This is demonstrated by the excitation profiles shown for the JB and BBJB sequences in the lower traces of Figures 2(a) and 2(b), respectively. Computer-optimized broadband sequences have now been developed to deal with this problem.¹² In summary, the BBJB experiment has many advantages and is rapidly superseding the conventional JB experiment as the method of choice for measuring T_{1Q} . Moreover, since this technique can be applied successfully to powder patterns (which have a continuous distribution of quadrupolar splittings), it will be useful for measuring the orientation dependence of T_{1Q} in smectic and lyotropic mesophases.

To demonstrate procedures for determining individual spectral densities measurements of relaxation times of a liquid crystal mixture, consisting of 25 mol% of perdeuterated 4-methyl-4'-cyanobiphenyl (1CB-*d*₁₁) and 75 mol% 5CB-*d*₆, will be outlined as a case study.¹³ 5CB-*d*₆ is selectively deuterated on the alkyl chain carbon at positions C-1, C-4 and C-5, as shown in the molecular structure. Figure 3 illustrates the measurement of T_{1Z} using a nonselective inversion pulse followed by quadrupole echo detection. The bottom trace is an equilibrium spectrum, and spectral assignments for each of the quadrupolar doublets are indicated. Dipolar fine structure is apparent on the 1CB transitions, but it can be shown that this does not interfere with the T_{1Z} measurements.

The top trace in Figure 3 shows a partially relaxed spectrum with relaxation delay $T = 1 \text{ ms}$, and all the transitions are inverted. After 10 ms the aromatic doublet of 1CB (peak 5) has recovered substantially while the other lines remain inverted. After 45 ms, the 1CB methyl lines (peak 2) are nulled while the methyl (C-5) deuterons of 5CB (peak 4), which have the longest T_{1Z} , are still inverted. In order to obtain accurate T_{1Z} values from these data, it is necessary to choose a set

Figure 2 Pulse sequences, 5CB- d_6 spectra, and quadrupolar order excitation profiles for (a) the conventional JB pulse pair and (b) the BBJB sequence. For (a) the pulse delay was $\tau = 46 \mu\text{s}$, and in (b) the total excitation time $5\tau = 46 \mu\text{s}$. The simulated quadrupolar order excitation profiles include the effects of finite pulse lengths (90° pulse width of $1.6 \mu\text{s}$). The spectra were recorded at 46.06 MHz

Figure 3 Molecular structures of the binary mixture of 1CB- d_{11} (25 mol%) and 5CB- d_6 . Partially relaxed spectra at 46.06 MHz from the inversion–recovery experiment with quadrupolar echo detection (IRQE) were taken in the nematic phase at 28.2°C . Relaxation delay times are indicated on the left of each trace. Spectral assignments for the labeled peaks in the equilibrium spectrum, shown in the bottom trace, are: (1) deuterons on the first methylene carbon on the alkyl chain of 5CB; (2) methyl deuterons of 1CB; (3) deuterons on the fourth alkyl chain carbon of 5CB; (4) methyl deuterons of 5CB; and (5) aromatic ring deuterons of 1CB

of relaxation delays which span at least one full decade of recovery for every line. T_{1Z} for each deuteron is then obtained by fitting to the equation

$$M(\infty) - M(T) = [M(\infty) - M(0)] \exp(-T/T_{1Z}) \quad (8)$$

Here $M(T)$ is the sum intensity of the quadrupolar doublet at time T , $M(\infty)$ is its thermal equilibrium value, and $M(0)$ is the intensity immediately after inversion. In principle, perfect inversion should give $M(0) = -M(\infty)$. However, erroneous T_{1Z} values are obtained if this is assumed and the data are fitted to a two-parameter equation. A nonlinear fit in which $M(0)$, $M(\infty)$, and T_{1Z} are simultaneously adjusted is more reliable. Typically, 10 or more T values are needed for accurate results.

In the 1CB/5CB mixture, at 28.2°C , T_{1Z} ranges from 9.8 ms for the 1CB aromatic deuterons to 209 ms for the 5CB methyl deuterons. Thus, it is not possible to construct one set of relaxation delays which is appropriate for every transition. Instead, the list must be expanded to include T values which are appropriate for all the relaxation times. In practice, this requires a few preliminary experiments to establish the approximate range of T_{1Z} values, and when the range is large, as many as 20–30 delays may be required. A common source of error in this type of experiment is failure

Figure 4 Partially relaxed spectra at 46.06 MHz from a BBJB experiment on the nematic phase of the binary mixture of 1CB-*d*₁₁ (25 mol%) and 5CB-*d*₆ at 28.2°C. Relaxation delay times are indicated on the left of each trace. Spectral assignments are identical to those given in Figure 3

to wait for full equilibrium between successive scans: it is essential to wait at least five times the longest T_{1Z} value if systematic errors are to be avoided. Thus for the 1CB/5CB mixture, where 2048 scans were accumulated for each of 20 T values, the recycle delay was 1 s and the total experiment time was approximately 12 h.

Next, the BBJB sequence is used to excite quadrupole order uniformly. The relaxation time T_{1Q} can be measured by monitoring the decay of the difference magnetization for each doublet. Typical partially relaxed spectra for the 1CB/5CB binary mixture are shown in Figure 4. Since the difference magnetization for each doublet decays rigorously toward zero, the exponential decay function can be fitted with just two adjustable parameters (the initial intensity and T_{1Q}). Construction of an appropriate list of relaxation delays is as important as for T_{1Z} measurements, and the total experimental time is usually comparable.

Spectral densities may be calculated from the relationships

$$J_1(\omega_0) = \frac{2R_{1Q}}{9\pi^2(e^2q_{zz}Q/h)^2} \quad (9)$$

and

$$J_2(2\omega_0) = \frac{1}{18\pi^2(e^2q_{zz}Q/h)^2}(3R_{1Z} - R_{1Q}) \quad (10)$$

Here $e^2q_{zz}Q/h$ is the quadrupole coupling constant in hertz. When proper precautions are taken, and the signal-to-noise ratio is favorable, it is possible to determine the relaxation rates, $R_{1Z} = 1/T_{1Z}$ and $R_{1Q} = 1/T_{1Q}$, with a precision of 2–5%. This is sufficiently accurate that the use of approximate values for the quadrupole coupling constant should be avoided. Estimated values, from data reported for more or less similar materials, can lead to significant uncertainty in the spectral densities. Wherever possible, low-temperature quadrupole echo lineshapes should be analyzed to determine static values of the relevant quadrupole coupling constants.

While numerous measurements of $J_1(\omega_0)$ and $J_2(2\omega_0)$ have been reported, determinations of $J_0(0)$ are relatively

scarce. Potential dynamic information inherent in this spectral density is very important in the study of liquid crystals. In particular, the spectral density at zero frequency should be exquisitely sensitive to long-wavelength modes of order director fluctuations. Even though this small-angle process contributes in first order only to $J_1(\omega_0)$, higher order calculations¹⁴ reveal contributions to $J_0(\omega)$ which can be large as ω tends to zero.

All methods for determining $J_0(0)$ rely on measuring the dephasing rate of one quantum coherence, and subtracting contributions from $J_1(\omega_0)$ and $J_2(2\omega_0)$. For example, making use of the spectral densities listed in Table 1, it can be shown that $J_0(0)$ is given by

$$J_0(0) = \frac{1}{9\pi^2(e^2q_{zz}Q/h)^2}(4R_2^0 - 2R_{1Z} - 3R_{1Q}) \quad (11)$$

where R_2^0 is the limiting decay rate obtained in a multi-pulse quadrupole echo sequence in the limit of zero pulse spacing ($2\tau \rightarrow 0$), much smaller than $(e^2q_{zz}Q/h)^{-1}$.¹⁵ Alternatively, if the transverse relaxation rate $R_2(\text{sel})$ of one line of the quadrupolar doublet is measured using a selective Carr–Purcell sequence, $J_0(0)$ is given by

$$J_0(0) = \frac{1}{27\pi^2(e^2q_{zz}Q/h)^2}[12R_2(\text{sel}) - 3R_{1Z} - 5R_{1Q}] \quad (12)$$

To date, there is no single method that is successful for measuring T_2 in all liquid crystalline systems. Figure 5 illustrates an efficient 2D procedure appropriate for spectra with many lines. The sample is perdeuterated fluorene dissolved in the nematic phase of 5CB. In this experiment a train of n equally spaced 90_y° refocusing pulses are applied during the evolution period and the acquisition is started at the top of the last echo. The evolution time must therefore be incremented in integral multiples of the echo spacing. For the 2D spectrum shown in Figure 5, the spacing was $2\tau = 300 \mu\text{s}$, and every fifth echo was recorded ($n = 1, 6, 11, \dots, 76$). Thus the spectral width in the f_1 frequency domain is $\pm 1/(20\tau) = \pm 333 \text{ Hz}$. The ordinary spectrum is recovered as a slice along $f_1 = 0$, and is displayed at the right edge of the contour plot (spectral assignments are indicated). Each peak has a Lorentzian profile in f_1 , and its T_2 can be determined simply from the linewidth at half maximum. However, before relying on these T_2 values to determine $J_0(0)$ it is necessary to consider the pulse spacing dependence of the relaxation time,¹⁵ and potential sources of systematic errors. In some cases, T_2 may be so short that only a few echoes can be observed, and the digital resolution in f_1 is then insufficient for accurate linewidth measurements. It is encouraging that the T_2 values determined in the frequency domain, from the 2D linewidths, are found to agree (within experimental error) with those determined in the time domain by fitting the line intensities as a function of relaxation delay.

Unresolved dipolar interactions are a potentially serious source of error in multiple pulse quadrupolar echo measurements of T_2 in liquid crystals. Dipolar precession is not refocused by the nonselective 90_y° pulses, and unresolved dipolar couplings produce apparent dephasing which can be confused with a true T_2 process. This problem is also unavoidable in nonselective two-pulse procedures where the echo amplitude

Figure 5 A 2D method for determining T_2 s in a multiline spectrum. The sample is perdeuterated fluorene- d_{10} in the nematic phase of 5CB. The normal ^2H NMR spectra (46.06 MHz) is obtained from the $f_1 = 0$ slice through the data matrix, and is shown to the right of the contour plot. T_2 of each line is obtained from the full width at half maximum of the Lorentzian lineshape for the corresponding slice in f_2 , as shown on the left. The pulse sequence for this experiment is shown, and for this data set the pulse spacing was $2\tau = 300 \mu\text{s}$, and every fifth echo was recorded

is monitored as a function of pulse spacing to give T_{2e} . The use of selective pulses, designed to monitor spin echoes from one-half of the quadrupolar doublet, circumvents this difficulty. However, in samples with small quadrupolar splittings and many lines it may not be possible to achieve adequately selective pulses. Alternatively, all precession of the transverse magnetization can be suppressed by using the multiple quadrupolar echo experiment with closely spaced 90_y pulses. This achieves effective spin locking when the pulse spacing is smaller than the inverse of the largest quadrupole splitting. In practice, this procedure requires a very robust temperature controller to avoid overheating the sample. A general, accurate method of measuring $J_0(0)$ in liquid crystals remains to be established, and this continues to be a topic of current research.

The decay rate of double quantum coherence for a single deuteron depends exclusively on $J_1(\omega_0)$ and $J_2(2\omega_0)$. Thus there is no additional information to be gained by measuring this relaxation rate that cannot be obtained more accurately from simple measurements of T_{1Z} and T_{1Q} . In a few carefully chosen systems, with well-resolved deuteron dipolar coupling, it has been possible to create and monitor the decay of

both double- (R_{1313}) and four-quantum (R_{1414}) coherences.¹⁶ This permitted determination of the cross-correlation terms in the motion of two different quadrupole coupling tensors, and provided insight into rotational anisotropy of small rigid solutes in liquid crystalline solvents. Unfortunately, this method cannot be readily extended to typical liquid crystal molecules because of extensive dipolar couplings, which are usually too small to be resolved and thus contribute to the apparent multiple-quantum linewidth.

4 SITE SPECIFIC SPECTRAL DENSITIES

Deuteron relaxation in liquid crystals gains much of its utility from the unambiguous way in which the spectral densities depend on the orientation of the EFG tensor with respect to molecule-fixed coordinates. By measuring spectral densities for deuterons with several different orientations, it is possible to obtain a very stringent test of models of rotational motion. The general orientation dependence, expressed in

equation (5), can be quite complex, and it is useful to consider the special case of a linear molecule. In this case, the EFG tensor has zero asymmetry parameter, and the largest component is collinear with the molecule-fixed Z axis ($\beta_{MP} = 0$). The fourfold summation in equation (5) then collapses to a single term:

$$J_m(m\omega_0) = J_{m00}(m\omega_0) \quad (13)$$

It can be shown that the spectral densities $J_{m00}(m\omega_0)$ are determined exclusively by processes which reorient the long molecular axis. These include order director fluctuations, which make a large contribution only to $J_{100}(\omega_0)$, and molecular reorientation which contributes to both $J_{100}(\omega_0)$ and $J_{200}(2\omega_0)$. Illustrative data for cyanoacetylene-*d* dissolved in a commercial nematic liquid crystal mixture (Merck Phase V)¹⁷ are shown in Figure 6. $J_1(\omega_0)$ clearly includes a frequency-dependent contribution which is absent from $J_2(2\omega_0)$. Numerous investigations of the deuteron relaxation of small rigid solutes in nematic phases have made use of this frequency dispersion to isolate the contributions from director fluctuations.

Measurements¹⁸ have demonstrated that director fluctuations do not play a major role in the deuteron relaxation of the liquid crystal molecules themselves. The rotational motion of typical nematogens is apparently slow enough to occur on approximately the same timescale as director fluctuations. It can then be shown that cross-correlation effects act to quench the contribution of director fluctuations, so that the spectral densities can be interpreted exclusively in terms of single-molecule rotation.¹⁹

Figure 6 Spectral densities $J_1(\omega_0)$ (open symbols) and $J_2(2\omega_0)$ (solid symbols) for cyanoacetylene-*d* in nematic Merck Phase V.¹⁷ Data were acquired at several Larmor frequencies: triangles, $\nu_0 = 4.6$ MHz; circles, $\nu_0 = 9.2$ MHz; squares, $\nu_0 = 38.4$ MHz. The experimental points are joined by lines to guide the eye. For reasons discussed in the text, $J_1(\omega_0)$ depends on the Larmor frequency while $J_2(2\omega_0)$ does not

Figure 7 Models used to describe molecular motion in oriented environments. (a) rotational diffusion (RD), (b) anisotropic viscosity (AV) and (c) the ‘third rate’ (TR) model

While a full discussion of molecular motion is beyond the scope of this article, three popular rotational models are illustrated in Figure 7: rotational diffusion (RD),²⁰ anisotropic viscosity (AV),²¹ and the ‘third rate’ (TR) model.²²

Small-step rotational diffusion of a symmetric rotor is fully characterized by two correlation times, $\tau_{\perp} = 1/(6D_{\perp})$ and $\tau_{\parallel} = 1/(6D_{\parallel})$, where $D_{\perp}$ and $D_{\parallel}$ are rotational diffusion constants. If the diffusion tensor is assumed to be diagonal in laboratory-fixed coordinates, where its principal components are related to anisotropic viscosity coefficients, the relevant correlation times for this ‘anisotropic viscosity’ model are still labeled $\tau_{\perp}$ and $\tau_{\parallel}$ but their physical meaning is different. Assuming that the nematic director remains parallel to the magnetic field, τ_{β} and τ_{α} in the TR model have the same physical significance as $\tau_{\perp}$ and $\tau_{\parallel}$ (respectively) in the AV model. The third rate is characterized by a correlation time τ_{γ} for rotation about the long molecular axis, which can occur in steps of arbitrary size as specified by a collision parameter p , where $0 \leq p \leq 1$.

The nematogen 2-fluorenyl 4'-tetradecyloxybenzoate-*d*₉ (FLOC₁₄-*d*₉) provides an excellent example of how spectral densities can be used to test these rotational models. Figure 8 shows the molecular structures and the assigned NMR spectrum in the nematic phase of a binary mixture of FLOC₁₄-*d*₉ and *p*-xylene-*d*₁₀ (~10 mol%). The temperature dependence of the spectra gives the orientational order parameters of both molecules.²³ By measuring and analyzing T_{1Z} and T_{1Q} for all

Figure 8 Quadrupole echo spectrum at 32.8 MHz with spectral assignments for a binary mixture of FLOC₁₄-d₉ and *p*-xylene-d₁₀ in the nematic phase. Analysis of relaxation data for this sample using the TR model provided correlation times for both the rigid solute and the flexible liquid crystal molecule²⁴

the lines as a function of temperature, it was possible to determine rotational correlation times for both components of the mixture.²⁴

Measurements on pure FLOC₁₄-d₉, which has deuterons at five different orientations of the EFG tensor, yielded 10 independent spectral densities at each temperature.¹⁸ A representative selection of the extensive data is shown in Figure 9 which gives the spectral densities for two molecular sites—the 3 ($\beta_{MP} = 54.65^\circ$) and 5,8 ($\beta_{MP} = 78.15^\circ$) positions. The points are experimental spectral densities, and the lines represent a nonlinear least-squares fit of the data from all positions to the TR model.

The problem of fitting the spectral densities to the various motional models is highly overdetermined, and the quality of the fit can be used to assess the validity of each model. Not surprisingly, it was found that no two-parameter model was capable of simultaneously fitting the spectral density data for all the sites. The TR model, with four independently adjustable parameters, provided by far the best fit. Figure 10(a) shows a 3D minimum $\Delta\chi^2$ surface (68% confidence boundaries) in the correlation time phase space (τ_α , τ_β , τ_γ), for FLOC₁₄-d₉ at 135.7°C.¹⁸ At this temperature the order parameter $S_{zz} = 0.523$, and the correlation times are $\tau_\alpha = 610 \pm 300$ ps, $\tau_\beta = 1050 \pm 250$ ps, and $\tau_\gamma = 266 \pm 20$ ps. Measuring the temperature dependence of the correlation times allowed

Figure 9 Individual spectral densities, $J_1(\omega_0)$ and $J_2(2\omega_0)$, for positions 3 and 5,8 of FLOC₁₄-d₉, as a function of inverse temperature. Closed circles are $J_1(\omega_0)$ measured at 46 MHz, closed triangles are $J_1(\omega_0)$ at 38.4 MHz, closed squares are $J_2(2\omega_0)$ at 46 MHz and closed diamonds are $J_2(2\omega_0)$ at 38.4 MHz. The open symbols, which are connected by dotted lines to guide the eye, are fits of the 46 MHz data, from all positions, to the third rate model of molecular reorientation. (Adapted from Goetz et al.¹⁸)

activation energies for the three independent rotations to be determined.

5 SAMPLE ROTATION EXPERIMENTS

When a liquid crystal sample is rotated in a magnetic field, the diamagnetic susceptibility anisotropy results in a torque on the director which tends to align it either parallel or perpendicular to the field. In nematic mesophases, the opposing viscous forces are too weak, and spontaneous realignment of the director occurs. This is unfortunate, because when the director can be rotated, profound changes are observed in both the NMR spectrum and relaxation times. Deuteron spectra with well-resolved doublets are observed only when the director is aligned with respect to the field. If it is not so aligned, the distribution of molecular orientations about the director

Figure 10 TR model parameters for pure FLOC_{14-d9} in the nematic phase at 135.7°C. (a) Constant $\Delta\chi^2$ boundary of 68% confidence in the 3D parameter space of the TR model, $(\tau_\alpha, \tau_\beta, \tau_\gamma)$. (b) Arrhenius plots of the temperature dependence of the motional correlation times; τ_α data are shown as squares, τ_β as circles, and τ_γ as triangles. The error bars correspond to the 68% confidence boundaries, and the lines are least squares fits of the data which give the activation energies. (Adapted from Goetz et al.¹⁸)

produces a distribution of doublet splittings, and the resulting characteristic spectra are reminiscent of the powder patterns observed in solid state ^2H NMR. Analysis of these lineshapes and rotation patterns can provide a wealth of information about the orientational distribution function. This technique has been especially successful in elucidating structure and organization in a magneto-aligned chiral smectic C phase, S_C^* .²⁵

Relaxation measurements as a function of sample orientation are relatively scarce, in part because methods for obtaining individual spectral densities from complex powder patterns have only been devised in the 1990s.²⁶ The information available from such experiments can be appreciated by considering the simple case of a uniaxial phase, such as smectic A or hexatic smectic B. It can then be shown²⁷ that the spectral densities are given by

$$J_0(\beta, 0) = \frac{1}{4}(1 - 3\cos^2\beta)^2 J_0(0) + 3\cos^2\beta \times \sin^2\beta J_1(0) + \frac{3}{4}(1 - \cos^2\beta)^2 J_2(0) \quad (14a)$$

$$J_1(\beta, \omega_0) = \frac{3}{2}\cos^2\beta \sin^2\beta J_0(\omega_0) + \frac{1}{2}(1 - 3\cos^2\beta + \cos^4\beta)J_1(\omega_0) + \frac{1}{2}(1 - \cos^4\beta)J_2(\omega_0) \quad (14b)$$

$$J_2(\beta, 2\omega_0) = \frac{3}{8}(1 - \cos^2\beta)^2 J_0(2\omega_0) + \frac{1}{2}(1 - \cos^4\beta) \times J_1(2\omega_0) + \frac{1}{8}(1 + 6\cos^2\beta + \cos^4\beta)J_2(2\omega_0) \quad (14c)$$

If T_{1Z} and T_{1Q} are analyzed to yield $J_1(\beta, \omega_0)$ and $J_2(\beta, 2\omega_0)$ as functions of sample rotation angle β , inversion of equations (14b) and (14c) will yield six spectral densities: $J_0(\omega_0)$, $J_1(\omega_0)$, $J_2(\omega_0)$, $J_0(2\omega_0)$, $J_1(2\omega_0)$, and $J_2(2\omega_0)$. It must be noted that these results are applicable only for uniaxial phases, and most phases which are rigid enough to support sample rotation have more complicated, biaxial symmetry. While this further complicates the orientation dependence of the spectral densities, it should not preclude using them to test motional models.

6 CONCLUSIONS

This article has discussed and summarized the existing experimental methods which are used to measure various deuteron relaxation times in liquid crystals. Accurate determination of appropriate combinations of relaxation rates allows the derivation of the individual spectral density functions $J_1(\omega_0)$, $J_2(2\omega_0)$, and, occasionally, $J_0(0)$. These spectral densities are Fourier transforms of rotational correlation functions and can be interpreted in terms of models of molecular motion. Currently, when appropriate precautions are taken, it is possible to measure spectral densities with an accuracy of 2–5%. This places very tight constraints on acceptable theoretical descriptions of molecular dynamics. In the nematic phase of thermotropic liquid crystals, performing these experiments as a function of temperature and magnetic field strength (ω_0) provides a rigorous test for models of molecular motion in the presence of an orientating potential. Extension of the measurements to more complex ordered smectic, lyotropic, and discotic mesophases offers the possibility of determining the orientation dependence of the relaxation rates, and represents a dramatic increase in the available information.

In conclusion, measuring ^2H NMR relaxation rates is a powerful and important method for investigating and understanding molecular dynamics in liquid crystal samples.

1 INTRODUCTION

Rowell and co-workers^{1,2} were first to demonstrate that deuterium is an excellent spin probe for studying liquid crystalline samples. They also used selectively deuterated compounds to simplify the proton NMR spectra. Early work in this field was devoted to measuring and interpreting spin-lattice relaxation rates³ of protons, and to revealing orientational ordering in various mesophases⁴ by means of deuterium splittings and spectral patterns. While proton NMR of liquid crystals shows broad partially resolved spectra, the deuterium NMR spectra are often characterized by well resolved quadrupolar doublets^{5,6} that may contain some dipolar fine structures [Figure 1(a)]. The deuteron ($I = 1$) Zeeman levels [Figure 1(b)] are perturbed by interaction of its nuclear quadrupolar moment Q with the asymmetric EFG at the deuteron site. The static Hamiltonian $\hat{\mathcal{H}}_0$ of the system is defined by

$$\hat{\mathcal{H}}_0 = \hat{\mathcal{H}}_Z + \langle \hat{\mathcal{H}}_Q(t) \rangle \quad (1)$$

where $\hat{\mathcal{H}}_Z$ is the Zeeman Hamiltonian and $\hat{\mathcal{H}}_Q$, the quadrupolar Hamiltonian, is time dependent due to thermally driven, randomly fluctuating molecular processes. Due to a nonzero $\langle \hat{\mathcal{H}}_Q(t) \rangle$ in a partially ordered system, the two nuclear transitions are displaced at equal distances from the Larmor frequency ($\omega_0/2\pi$) as shown in Figure 1. The EFG tensor for most C–D bonds is axially symmetric, with the unique principal axis along the C–D bond direction. The quadrupolar splitting for a static C–D bond can take a maximum value of $\frac{3}{2}\chi$ or about 260 kHz, which is much less than its Larmor frequency of 46 MHz in a magnetic field of 7.1 T. For comparison, dipolar splitting between two deuterons in a methylene group is at most a few kilohertz, D–H dipolar splitting for a similar geometry is about 10 kHz, and the chemical shift is of the order of 1 kHz. It is therefore possible to neglect the chemical shift dispersion and the dipolar interaction with other nuclei and to treat the deuteron as an isolated spin-1 nucleus. The theoretical analysis of such a system is relatively simple. The quadrupolar splitting $\Delta\nu_i$ of the i th C–D bond may be approximated by^{7,8}

$$\Delta\nu_i = \frac{3}{2}\chi S_{zz}(3 \cos^2 \theta_i - 1)/2 \quad (2)$$

Figure 1 (a) The structure of MBBA and a typical deuterium NMR spectrum of MBBA- d_{13} in its nematic phase. (b) Energy level diagram of a deuteron spin ($\eta = 0$) in a large magnetic field. $\omega_0/2\pi$ is the Larmor frequency

where the contribution from the $S_{xx} - S_{yy}$ term is neglected, S_{zz} is the orientational order parameter of the long molecular axis with respect to the nematic director (see below), and θ_i represents the angle between the C_i –D bond and the molecular z axis. The angular brackets denote a statistical average over all allowed conformations in a flexible mesogen.

Spin relaxation has long been recognized as a useful technique for studying dynamic processes in liquid crystals.^{7,8} A partial list of such processes⁸ includes the order director fluctuations (ODFs), translational diffusion, order parameter fluctuations near phase transitions, molecular reorientation, and internal rotations of alkyl end chains. Deuteron is particularly suitable for getting detailed information about molecular motion in liquid crystals, since its relaxation is governed by intramolecular mechanisms, and multipulse techniques⁷ may be used to determine individual spectral densities of motion from partially relaxed deuteron NMR spectra for all the resolved doublets. The quadrupolar relaxation Hamiltonian for a spin-1 system is defined by the time dependent part of $\hat{\mathcal{H}}_G(t)$ with respect to its average value $\langle \hat{\mathcal{H}}_Q(t) \rangle$:

$$\hat{\mathcal{H}}'_Q(t) = \hat{\mathcal{H}}_Q(t) - \langle \hat{\mathcal{H}}_Q(t) \rangle \quad (3)$$

The deuterium spin-lattice relaxation rates are given by^{9,12}

$$\frac{1}{T_{1Z}} = J_1(\omega_0) + 4J_2(2\omega_0) \quad (4)$$

$$\frac{1}{T_{1Q}} = 3J_1(\omega_0)$$

where an axially symmetric quadrupolar interaction ($\eta = 0$) is assumed. The spectral densities of motion J_{mL} ($m_L \omega_0$) are Fourier transforms of the autocorrelation functions $G_{mL}(t)$ which involve second-rank tensor components $D_{mL0}^2(\Omega(t))$ in the relaxation Hamiltonian. The part of $\hat{\mathcal{H}}'_Q(t)$ that connects spin states with $\Delta m_I = 1$ has a fluctuation spectrum described by $J_1(\omega_0)$, while the part that connects states with $\Delta m_I = 2$ is described by $J_2(2\omega_0)$. These spectral parameters and $J_0(0)$ at zero frequency (obtained in principle from one quantum spin echo or quadrupolar echo experiments) are determined without a particular choice of motional model. They must be accurately measured as a function of temperature at different Larmor frequencies, and may be used to provide critical tests of any proposed model of molecular motion. For systems with coupled deuterons, there are additional terms^{13,14} in the relaxation expressions that arise from cross-correlation functions describing pairwise correlation in the motion of EFG tensor components at each deuteron. This additional information may serve as a further check of the proposed motional model.

2 ORIENTATIONAL ORDERING

One of the common features in liquid crystals is the existence of a preferred orientation of molecules along a spatial direction specified by a unit vector known as the director $\mathbf{n}$. Deuteron NMR spectroscopy has played a major role in establishing molecular field theories^{8,15,16} for liquid crystals. These mean field theories can predict the temperature dependences of order parameters of rigid solutes and solvent molecules. The ordering of molecules in mesophases may in general be described by an orientational distribution function $f(\Omega)$ which depends on Eulerian angles $\Omega(\equiv \phi, \theta, \psi)$. The $f(\Omega)$ can be expanded in terms of Wigner rotation matrices of rank L

$$f(\Omega) = \sum_{L=0}^{\infty} \sum_{m,m'=-L}^L \frac{2L+1}{8\pi^2} a_{Lm'm} D_{m'm}^L(\Omega) \quad (5)$$

where the expansion coefficients $a_{Lm'm} = \langle D_{m'm}^{L*}(\Omega) \rangle$ are the microscopic order parameters of rank L . The order parameters of rank two and four can in principle be measured, but higher rank order parameters are not as easily accessible by experiments. The potential of mean torque $V(\Omega)$ can be defined by writing $f(\Omega)$ as

$$f(\Omega) = \exp[-\beta V(\Omega)] / \int d\Omega \exp[-\beta V(\Omega)] \quad (6)$$

where $\beta = 1/k_B T$. $V(\Omega)$ represents the orientational potential of a single molecule. In the Maier-Saupe theory^{17,18} of nematics, $V(\Omega)$ takes on a simple form:

$$V(\cos \theta) = -\epsilon \langle P_2(\cos \theta) \rangle P_2(\cos \theta) \quad (7)$$

where the parameter ϵ scales the strength of intermolecular interaction. The theory used a mean field approach and assumed that attractive dispersion forces among molecules are responsible for the nematic order. It was successful in

predicting a first-order phase transition between a nematic and an isotropic phase, as well as the temperature dependence of the nematic order parameter $\langle P_2 \rangle (\equiv S_{zz})$. Using equation (2) as a first approximation, $\langle P_2 \rangle$ can be calculated^{1,2} from the observed quadrupolar splittings in liquid crystals. A general set of 25 rank-two order parameters⁸ was defined by Saupe:

$$S_{ij}^{\alpha\beta} = \frac{1}{2} \langle 3i_{\alpha} j_{\beta} - \delta_{\alpha\beta} \delta_{ij} \rangle \quad (8)$$

where (α, β) refer to a space-fixed axis system (X, Y, Z) , (i, j) refer to a molecule-fixed axis system (x, y, z) , i_{α} denotes the projection of a unit vector $\mathbf{i}$ along the α axis, and the angular brackets represent an ensemble average. For uniaxial phases where $\mathbf{n} \parallel Z$ axis, equation (8) gives the simple Saupe order matrix $S_{ij} (= \frac{1}{2} \langle 3i_z j_z - \delta_{ij} \rangle)$.

2.1 Rigid Molecules in Uniaxial Phases

For a rigid molecule (or a rigid fragment of a molecule) ordered in a uniaxial liquid crystalline phase, the partially averaged component $\langle A_{\parallel} \rangle$ parallel to the director of any second rank tensor $\mathbf{A}$ is given by

$$\langle A_{\parallel} \rangle = A_0 + \frac{2}{3} \sum_{ij} A_{ij} S_{ij} \quad (9)$$

where A_0 is the isotropic average of $\mathbf{A}$. For the EFG tensor $\mathbf{q}$, A_0 is zero and the splitting $\Delta\nu = \frac{3}{2} e^2 Q / h \langle q_{\parallel} \rangle$ can be calculated using equation (9). The unknown S_{ij} elements can be determined from measuring enough independent values of $\langle q_{\parallel}^i \rangle$ where the superscript refers to sites in a molecule. This is usually possible for a rigid solute dissolved in a liquid crystal, where the principal axes of symmetry of the solute may be located with certainty based on its molecular symmetry. Hence deuterium NMR can provide precise measurements of S_{zz} and $S_{xx} - S_{yy}$ for a rigid molecule. Figure 2 illustrates the determination of $S_{xx} - S_{yy}$ and S_{zz} for anthracene- d_{10} in several nematogens. The solid curves are predictions based on the mean field theory of biaxial solutes where the λ parameter is a measure of the deviation in molecular symmetry of the solute from cylindrical symmetry. That the solute ordering depends on the solvent is an indication that the solute-solvent interactions cannot be dominated only by dispersion forces. For flexible mesogens, it may be possible to determine a local order matrix for a rigid fragment of the molecule provided the principal axes can be located on the fragment based on its symmetry. This is often difficult due to a lack of measurable nuclear couplings. A clear exception to this is the study of a perdeuterated fluorene group in the mesogen 2-fluorenyl-4'-tetradecyloxy benzoate- d_9 (FLOG₄).²⁰ Because of the large number (eight) of distinct deuteron sites, the location of the long molecular axis could be adjusted for the average conformer in a frame fixed to the fluorene group, and the local order parameters were unambiguously determined.

2.2 Flexible Molecules in Uniaxial Phases

Mesogenic molecules are usually composed of an aromatic core and one or more flexible alkyl chains. Due to internal

Figure 2 (a) Molecular structure of anthracene-*d*₁₀ and the deuterium spectrum at 30.7 MHz from deuterons 1, 4, 5, 8, 9, and 10 in anthracene-*d*₁₀ dissolved in Phase V. (b) Variation of S_{zz} with $S_{xx} - S_{yy}$ for anthracene-*d*₁₀ dissolved in ZLI 1167 (□), E9 (○) and Phase V (◇).¹⁹

rotations, the chain does not always exist in an all-*trans* conformation. It is generally accepted that a single order tensor may not be enough to describe orientational ordering of different configurations. In equation (9), the average of $A_{||}$ must also be carried out over an ensemble of molecules having all allowed configurations. The rotational isomeric state (RIS) model of Flory²¹ is used to generate all chain configurations. Since a single $A_{||}$ value would not provide quantitative information on the orientational order of the molecules, a molecular model is therefore required. Such a model using the additive potential method^{15–19} was pioneered by Marcelja and later improved by Emsley and Luckhurst. The potential of mean torque which is responsible for the alignment of a conformer has its origin from the molecular field of its neighbors. It is constructed by adding up local interaction tensors of the carbon–carbon segments and the rigid aromatic core segment, which are specified by model parameters X_c and X_a , respectively. Each rigid (*n*th) conformer has its own order matrix S^n and its equilibrium probability of occurrence $P_{eq}(n)$. Equilibrium statistical mechanics is used to do the ensemble average in calculating the quadrupolar splittings $\Delta\nu_i$. The parameters X_c , X_a and E_{tg} (the energy difference between a *gauche* and a *trans* state) are varied to optimize the fits to the

Figure 3 Plot of $\langle P_2 \rangle$ versus $\langle S_{xx} \rangle - \langle S_{yy} \rangle$ for the averaged MBBA molecule.²²

experimental splittings.⁸ For example, such analysis²² has been carried out for the splittings of MBBA (Figure 1). Knowing $S_{\alpha\beta}^n$ and $P_{eq}(n)$, it is possible to find a conformationally average order matrix $\langle S \rangle$ by doing the statistical average in a common molecular frame. The principal components $\langle P_2 \rangle$ and $\langle S_{xx} \rangle - \langle S_{yy} \rangle$ of the ‘average’ molecule can be obtained by diagonalizing the $\langle S \rangle$ matrix. Figure 3 shows the plot of $\langle S_{xx} \rangle - \langle S_{yy} \rangle$ versus $\langle P_2 \rangle$ of MBBA. It is interesting to note that the molecular biaxial order parameter, $\langle S_{xx} \rangle - \langle S_{yy} \rangle$, of the ‘average’ molecule is quite small for this flexible mesogen.

2.3 NMR in Biaxial Phases

Biaxial nematics, some smectic phases, such as S_G , and certain discotic phases⁸ show phase biaxiality. Deuterium NMR may be used to detect phase biaxiality through the measurement of a nonzero motionally induced asymmetry parameter η^{LC} in the nuclear quadrupolar interaction whose EFG may have $\eta = 0$ in the solid state. Suppose that the molecule is rigid and the principal axes (*X,Y,Z*) of the liquid crystalline phase are chosen to coincide with the principal axes of the average EFG tensor. Letting the polar angles of the magnetic field in the (*X,Y,Z*) system be (θ_0, ϕ_0) , the splitting is given by⁸

$$\delta\nu(\theta_0, \phi_0) = \frac{3}{4}\chi^{LC}\{(3\cos^2\theta_0 - 1) + \eta^{LC}\sin^2\theta_0\cos 2\phi_0\} \quad (10)$$

where χ^{LC} , a motionally averaged quadrupole coupling constant, and η^{LC} are defined by

$$\chi^{LC} = \chi \sum_m \overline{D_{0,m}^2(\theta, \psi) D_{m,0}^2(\beta, \alpha)} \quad (11)$$

$$\eta^{LC} = \sqrt{\frac{3}{2}} \frac{\chi}{\chi^{LC}} \sum_m [\overline{D_{2,m}^2(\phi, \theta, \psi)} + \overline{D_{-2,m}^2(\phi, \theta, \psi)}] D_{m,0}^2(\beta, \alpha)$$

where (ϕ, θ, ψ) are Euler angles that transform between a molecular frame (*x,y,z*) and the liquid crystalline (*X,Y,Z*)

Figure 4 Experimental angular dependence of the deuterium NMR spectrum in the S_G phase of 5O.7- d_4 (aniline ring deuterated) at 31 °C.²⁴

frame, and (β, α) are the polar angles of the C–D bond in the molecular frame. Phase biaxiality is reflected by $D_{\pm 2, m}^2$ in η^{LC} , and the effect of η^{LC} on $\Delta\nu$ is maximum when the director is oriented normal to the magnetic field (i.e. $\theta_0 = 90^\circ$). It is noted that symmetry considerations involving both the nature of the molecules and of the liquid crystalline phases can considerably simplify the evaluation of the order parameters $D_{m', m}^2(\phi, \theta, \psi)$. η^{LC} takes on a simple form if the (x, y, z) frame is chosen to be the principal frame of the order matrix. Further simplification can be made if the molecule is a cylindrical rod [$m = 0$ in equation (11)]. Then

$$\chi^{LC} = \chi S_{zz}^{ZZ} (3 \cos^2 \beta - 1)/2$$

$$\eta^{LC} = \sqrt{\frac{3}{2} [D_{2,0}^2 + D_{-2,0}^2]} / S_{zz}^{ZZ} = (S_{zz}^{XX} - S_{zz}^{YY}) / S_{zz}^{ZZ} \quad (12)$$

The $S_{zz}^{XX} - S_{zz}^{YY}$ term represents anisotropic fluctuations of the molecular z axis relative to the principal axes (X, Y, Z) of the average EFG tensor. Edge singularities (Figure 4) are predicted for the spectral pattern when $\theta_0 \neq 0$. The separation between edge singularities at $\theta_0 = 90^\circ$ is a direct measure of η^{LC} . Such a spectral pattern was first observed in an S_G phase²³ with a deuterated solute in the mesogen 6O.6. A η^{LC} value of 0.2 was obtained²⁴ in the S_G phase of 5O.7- d_4 (Figure 4). Phase biaxiality had been investigated in other smectic phases by Doane²⁵ and in discotics by Luz.²⁶

3 SPIN RELAXATION AND MOLECULAR MOTION

Both nuclear spin–lattice and spin–spin relaxation rates are governed by random motion of spin-bearing molecules. Typically, a molecule remains in one state of motion for a short time (10^{-10} – 10^{-12} s). After this time, it suffers a collision with one of its neighbors, which changes its state of motion. When the molecule persists in some state of motion for a time of 10^{-10} s, its motional frequency spectrum is expected to contain components ranging from zero to 10^{10} Hz, which are covered by typical NMR experiments. Several dynamic processes are known to cause deuteron spin relaxation in liquid crystals. The process known as director fluctuations is unique to liquid crystals and was first used to explain light scattering from liquid crystals. Other processes include order parameter fluctuations, molecular reorientation, and internal rotations. The latter two motions involve individual molecules as in normal liquids, while director fluctuations involve collective motions of a large number of molecules. These collective motions are influenced by macroscopic properties like elastic

constants and anisotropic viscosities of the liquid crystalline medium. At best, director fluctuations can provide indirect information on the anisotropic interactions among molecules. On the contrary, molecular motion must reflect the shape of the instantaneous potential of mean torque on each molecule. Thus, it is sensitive to the nature of anisotropic interactions. Here, spin relaxation due to small cross terms between different processes will be ignored⁸ for simplicity.

3.1 Solute Dynamics

To avoid dealing with internal rotations, deuterated rigid solutes dissolved in thermotropic liquid crystals were studied^{7, 27} by spectral density measurements. Solute reorientation and director fluctuations were used to account for the observed frequency and temperature dependences of $J_1(\omega)$ and $J_2(2\omega)$. It is now well known that director fluctuations under the small-angle approximation produce a characteristic $\omega^{-1/2}$ dependence in $J_1(\omega)$ only. Reorientation motion is often described in terms of a symmetric top reorienting in an anisotropic potential of Maier–Saupe type using a small-step rotational diffusion model.⁸ This model uses a rotational diffusion tensor for the molecule which is diagonalized in a molecule-fixed frame. For weakly ordered solutes, their reorientation in a nematic solvent is often rapid to give frequency-independent spectral densities. For example, deuteron spin relaxation of *p*-diethynylbenzene (DEB- d_2 , deuterated in the two alkyne sites) in the nematic phase of Phase V⁷ clearly showed that $J_1(\omega)$ has a pronounced frequency dependence, while $J_2(2\omega)$ is essentially independent of frequency. This observation provides compelling evidence of director fluctuations in relaxing the deuterons in DEB- d_2 . Smectic phases can be used to provide higher ordering of solute molecules. Similar frequency behaviors for J_1 and J_2 were obtained for DEB- d_2 in the four mesophases of 4O.8. However, J_2 showed more frequency dependence when DEB- d_2 was dissolved in 8CB.⁸ A definitive explanation of the differences in these J_2 values has not yet been found. In general, analyses of experimental spectral density data would lead to rotational diffusion constants (or rotational correlation times $\tau_{\parallel}$, $\tau_{\perp}$) and a material factor A_{DF} that characterizes the strength of director fluctuations. For example, the ratio $\tau_{\perp}/\tau_{\parallel}$ is about 10 for DEB- d_2 in the nematic phase of Phase V.

3.2 Solvent Dynamics

The detection of director fluctuations in liquid crystals by means of deuteron spin relaxation in mesogens at conventional frequencies (10–50 MHz) has not met with success. This can be attributed to two factors: (1) the numerical value A_{DF} is small because most C–D bonds are oriented at an unfavorable angle to the long molecular axis; this is true for aromatic deuterons in mesogens such as 4-pentyl-4'-cyanobiphenyl (5CB), MBBA, etc., and (2) the contribution from director fluctuations to deuteron relaxation is masked by a much larger contribution due to relatively slow motions of large, sluggish molecules and fast internal motions within these molecules. To alleviate the difficulty associated with a small contribution from director fluctuations in the megahertz region, deuteron field cycling techniques have been applied²⁸

to several nematogens. The techniques involve fast switching of the Zeeman field between high- and low-field levels so that detection of the NMR signal is done at a high magnetic field while the spin system is allowed to relax in a low field (in the kilohertz region). These data seem to support the findings based on the proton field cycling studies of liquid crystals that director fluctuations are slow motional processes and are effective for spin relaxation only in the kilohertz region.

To treat deuteron spin relaxation of solvent molecules in the megahertz region it is often possible to ignore the small contribution from director fluctuations. This assumption is probably necessary in modeling spectral densities of motion for various deuterated sites in flexible mesogens. In particular, correlated internal rotations in flexible chains of liquid crystals are complex to treat theoretically. Furthermore, different motional models⁸ for reorientation of solvent molecules are possible. Besides the commonly used small-step rotational diffusion model, the anisotropic viscosity model of Freed and co-workers⁸ is a distinct alternative. Freed used a rotational diffusion tensor that is diagonalized in the director frame to reflect the anisotropic viscosity of the liquid crystalline medium. Another motional model known as the ‘third-rate’ model is a simple extension of the Freed model. It has a fast rotation around the long molecular axis in addition to its motions around and toward the director. Numerous deuteron relaxation studies have been carried out in recent years to investigate molecular motion in liquid crystals. Table 1 briefly summarizes thermotropic liquid crystals in which spectral density measurements were reported.

As an example, the spectral density data of MBBA at 15.3 and 46 MHz are reproduced in Figure 5. The data are typical for thermotropic liquid crystals studied thus far. Both $J_1(\omega)$ and $J_2(2\omega)$ decrease with increasing temperature and are frequency dependent with a weaker dependence in $J_2(2\omega)$. To account for the observed site dependences of $J_1(\omega)$ and $J_2(2\omega)$, a model is required to treat internal motions in the butyl chain. A superimposed rotations model³³ was used to describe fluctuations in the orientations of the C–D bonds due to overall and internal modes of motion in the chain-deuterated nematogen 5CB. Here the internal dynamics of the pentyl chain was treated by assuming that rotations about each C–C bond are independent of each other and could be superimposed onto the rotational diffusion of the whole molecule. This motional model is, however, unrealistic and inconsistent with how quadrupolar splittings were modeled using the RIS model of Flory. The RIS model has been extended^{42–44} to the time domain for liquid crystalline samples. A master

equation may be used to describe transitions among all allowed configurations in the alkyl chain. The model of Nordio and co-workers⁴⁴ is inherently complex because their master equation includes configuration dependent frictional effects. The solution of the rotational diffusion problem requires a matrix representation in the full space of angular and site functions. Because of the large dimensionality of their matrix representation, the computational effort was extremely demanding. The decoupled model⁴² of Dong uses three phenomenological rate constants to describe elementary jump modes: one-bond (k_1), two-bond (k_2), and three-bond (k_3) motions. The dimension of the rate matrix which is constructed in terms of these jump rate constants has the advantage of being much smaller. Both approaches,^{34,42–44} however, give similar theoretical predictions for 5CB regarding site and frequency dependences of $J_1(\omega)$ and $J_2(\omega)$ as well as the observed discontinuity³³ in the spin–lattice relaxation rates at the nematic–isotropic phase transition.

The decoupled model has been successfully applied²² to interpret the spectral densities of methylene deuterons (Figure 5) in MBBA, which are given by

$$J_{m_L}^{(i)}(m_L\omega) = \frac{3\pi^2}{2} \chi_i^2 \sum_{m_M} \sum_{n=1}^{27} c_{m_L m_M} \left| \sum_{l=1}^{27} d_{m_M 0}^2 (\beta_{M,Q}^{(i)l}) \exp[-im_M \alpha_{M,Q}^{(i)l}] x_l^{(1)} x_l^{(n)} \right|^2 \sum_j a_{m_L m_M}^{(j)} [(\tau_{m_L m_M}^{(j)})^{-1} + |\lambda_n|] / \{(m_L\omega)^2 + [(\tau_{m_L m_M}^{(j)})^{-1} + |\lambda_n|]^2\} \quad (13)$$

where $\beta_{M,Q}^{(i)l}$ and $\alpha_{M,Q}^{(i)l}$ are the polar angles of the C–i–D bond of the conformer l (there are 3^3 conformers in the butyl chain when the first dihedral angle at the junction of the aniline ring is allowed to sample three RISs) in a molecule-fixed frame whose z_M axis is along the ring *para* axis, λ_n and $\mathbf{x}^{(n)}$ are the eigenvalues and eigenvectors from diagonalizing a symmetrized rate matrix, $c_{m_L m_M}$ are the mean square of the Wigner rotation matrices, and the a , b and c coefficients are tabulated as functions of $\langle P_2 \rangle$ for a Maier–Saupe potential.⁴⁵ The correlation times $\tau_{m_L m_M}^{(j)}$ take on slightly different forms; the small-step rotational diffusion model uses

$$(\tau_{m_L m_M}^{(j)})^{-1} = [6D_{\perp}/b_{m_L m_M}^{(j)} + m_M^2(D_{\parallel} - D_{\perp})] \quad (14)$$

and the third-rate model uses

$$(\tau_{m_L m_M}^{(j)})^{-1} = h_{m_M} + [6D_{\beta}/b_{m_L m_M}^{(j)} + m_L^2(D_{\alpha} - D_{\beta})] \quad (15)$$

Table 1 Summary of Deuterium Spectral Density Measurement in Thermotropic Liquid Crystals

Figure 5 Plots of spectral densities versus the reciprocal temperature in the nematic phase of MBBA- d_{13} . Open symbols denote spectral densities $J_1(\omega_0)$, while solid symbols denote the corresponding $J_2(2\omega_0)$. $\circ$ and ∇ and $\square$ denote the C-0 and C-2 and C-4 data at (a) 15.3 MHz and (c) 46 MHz. $\bullet$ and $\blacktriangledown$ denote the C-1 and C-3 data at (b) 15.3 MHz and (d) 46 MHz. Solid curves denote theoretical predictions based on the third-rate model and three jump rates for internal rotation.²²

where $h_0 = 0$, $h_1 = D_\gamma$, and $h_2 = (3p + 1)D_\gamma$, with $p = 0$ corresponding to strong collision and $p = 1$ to small-step rotational diffusion for the γ motion. The D s are rotational diffusion constants that are principal components of the rotational diffusion tensor of an ‘average’ molecule. The methine (C-0) deuteron has no internal motion, and the C-0–D bond reflects the motion of the aromatic core, giving

$$J_{m_L}^{(0)}(m_L\omega) = \frac{3\pi^2}{2} \chi_0^2 \sum_{m_M} c_{m_L m_M} [d_{m_M 0}^2 (\beta_{M,Q})]^2 \times \sum_j a_{m_L m_M}^{(j)} [\tau_{m_L m_M}^{(j)}]^{-1} / [(m_L\omega)^2 + (\tau_{m_L m_M}^{(j)})^{-2}] \quad (16)$$

where $\beta_{M,Q}$ is the angle between the C–D bond and the z_M axis. Using equations (13) and (16), the fits between the calculated and experimental spectral densities are optimized by varying the rotational diffusion constants and the jump rate constants at each temperature.

Both the small-step rotational diffusion and third-rate models were examined. Both models were found to describe molecular reorientation of MBBA. The solid curves in Figure 5 are theoretical spectral densities based on equations (13) and (16) using $\tau_{m_L m_M}^{(j)}$ given by the third-rate model [equation (15)], X_a , X_c , and $\langle P_2 \rangle$ given by modeling the quadrupolar splittings ($E_{lg} = 2550 \text{ J mol}^{-1}$, $E_{g\pm g\pm} = 6000 \text{ J}$

mol^{-1}). D_α and D_β are roughly the same ($\approx 5 \times 10^7 \text{ s}^{-1}$ in the middle of the nematic phase), while D_γ is two orders of magnitude larger. D_α refers to the motion of the long molecular axis around the director, while D_β refers to its motion toward the director. These rotational diffusion constants decrease with decreasing temperature as expected for a thermally activated rotational process. The Nordio model has been used to derive motional parameters at different temperatures in 5CB³⁴ and 4-*n*-hexyloxy-4'-cyanobiphenyl (6OCB).³⁵ In studying the reorientation process in the smectogen 5O.7, the spectral densities of the methine and ring deuterons were measured as a function of temperature at two different Larmor frequencies in the megahertz region.³¹ It was found that the large frequency dependence in $J_1(\omega)$ can only be rationalized by including director fluctuations. The third-rate model seems to produce physical rotational diffusion constants in the nematic, smectic A, and smectic C phases of 5O.7.

4 NOVEL NMR EXPERIMENTS

Some applications of newer NMR techniques to the study of liquid crystalline samples are now outlined. The proton NMR spectra of solute molecules dissolved in liquid crystals are usually complex, and iterative fitting of the NMR spectra must be used to extract dipolar couplings. Spectral simplification is possible by using partially deuterated solutes instead. When this is not practical, multiple quantum NMR spectroscopy⁴⁶ can greatly simplify spectra of complex spin systems. Multiple quantum NMR is concerned with the observation of forbidden nuclear transitions, i.e. $\Delta m_I \neq 1$. Multiple quantum coherences can only be detected indirectly. To detect all orders of multiple quantum transitions, special forms of two-dimensional NMR (2D NMR) spectroscopy are required. The high-order multiple quantum spectrum is simple due to the decrease in number of nuclear transitions with increasing order. Multiple quantum transitions of deuterons are now described.

In oriented systems, the quadrupole Hamiltonian leads to a splitting of the single quantum transitions [see Figure 1(b)]. Double quantum spectra of a deuteron ($\Delta m_I = 2$) have the advantage of eliminating quadrupolar effects. This is obvious from the deuterium energy diagram for a spin-1 system, since the quadrupolar shifts on $m_I = 1$ and $m_I = -1$ energy levels are equal. Any coherence established between these two levels will evolve at twice the Larmor frequency (as modified by chemical shift). Single- and double-quantum spectra were used⁶ to study chain conformation in four members of the *n*O.7 series. It was noted that the distribution in the quadrupolar splitting is the dominant contribution to the deuteron linewidth of the single quantum spectrum. The distribution is due to a spread in the orientation of the long molecular axes in the liquid crystalline sample. Because a double quantum spectrum is not affected by quadrupolar effects, it has better spectral resolution and therefore may yield long-range dipole–dipole couplings among deuterons. Figure 6 shows a comparison of single- and double-quantum spectra of the α signal of 5O.7- αd_2 [Figure 6(a)] and the γ signal of 5O.7- $\alpha d_2 \gamma d_1$ [Figure 6(b) and (c)]. The improved resolution of the γ signal in the double quantum spectra is remarkable, and allows measurements of long-range deuterium dipolar couplings. For a two-coupled deuteron system, multiple quantum transitions can

Figure 6 Single quantum (left) and double quantum (right) spectra for (a) the α signal of 5O.7- αd_2 at 57 °C, and the γ signal in 5O.7- $\alpha d_2 \gamma d_1$ at (b) 57 °C and (c) 41 °C, respectively. The stick diagrams give the corresponding theoretical spectra⁶

reveal the correlation of relaxation mechanisms acting on two deuterium nuclei. Besides the three autocorrelation terms $J_0^A(0)$, $J_1^A(\omega)$, and $J_2^A(2\omega)$, which describe the motion of the EFG tensor of either deuteron, the three cross-correlation terms $J_0^C(0)$, $J_1^C(\omega)$, and $J_2^C(2\omega)$ describe correlation between the motion of the two EFG tensors. There are many relaxation studies of deuterated solutes in thermotropic liquid crystals.^{13,14,27} For example, zero-, two-, and four-quantum linewidths may be used to determine the three cross-correlation terms^{13,14} in acetonitrile- d_3 .

2D NMR spectroscopy is now common in the study of liquid crystals. Using ^{13}C nuclei, the carbon–proton dipolar couplings can be obtained by means of the near magic angle spinning and the separated local field spectroscopy. Rapid sample spinning near the magic angle (54.7°) was incorporated to improve spectral resolution⁴⁷ so that coupling between indirectly bonded C–H pairs could be observed. A sample that has a chiral fluorinated solute dissolved in a liquid crystal was used to carry out a 2D ^{19}F spin echo⁴⁷ experiment in conjunction with the near magic angle spinning. This allows spectral analysis of small molecules to give residual dipolar coupling D_{ij} between nuclei i and j , and the isotropic spin–spin coupling J_{ij} . A deuteron 2D spin echo experiment on PAA- d_{14} allows assignment¹⁹ of quadrupolar splittings in the NMR spectrum of perdeuterated p -azoxyanisole. The same technique has been used in the nematic phase of β -deuterated 5CB dispersed in polymers⁴⁸ and in model bilayer membranes⁴⁹ to determine the homogeneous linewidth of the individual lines. Another form of deuteron 2D experiment is 2D exchange spectroscopy,^{50–52} which is capable of detecting slow molecular processes by monitoring the orientation of a C–D bond via its NMR frequency. A typical 2D time domain spectroscopy experiment involves four distinct periods [preparation, evolution (t_1), mixing, and detection (t_2)], leading to a time domain signal $s(t_1, t_2)$. Fourier transform of $s(t_1, t_2)$ gives $s(\omega_1, \omega_2)$, a 2D frequency spectrum. The

Figure 7 Experimental (left) and stimulated (right) spectra for (a) PS3 and (b) PS6 taken at 250 K with a mixing time of 100 ms. Contour plots are shown as insets⁵²

spectrum provides information relating the frequency ω_e in the evolution period just before mixing and the frequency ω_d in the detection period just after mixing. When ω_e is identical to ω_d , this gives rise to a spectrum on the diagonal of a 2D spectrum; otherwise, off-diagonal intensity can be formed in the form of straight ridges and ellipses.^{50,52} The detection of off-diagonal intensity is practical for motions that have a correlation time of the order of milliseconds or longer. As an example, deuteron 2D exchange spectroscopy in glass-forming liquid crystalline side-group polymers is described.⁵² Figure 7 shows the experimental and simulated 2D spectra for poly(4-alkyloxybenzoic acid 4'-methoxyphenyl- d_4 ester)siloxane (PS n) with $n = 3$ and 6. Both PS3 and PS6 were magnetoaligned in a strong magnetic field by slow cooling from the isotropic melt into the glassy state. The glassy state of the PS6 is a frozen smectic C phase, while the glassy state of the PS3 is a frozen nematic phase. Off-diagonal intensity in the form of a partial elliptical pattern can be simulated by assuming a Gaussian distribution for the orientation distribution of the long axis of the mesogenic unit. Because the orientational order $\langle P_2 \rangle$ of PS3 is lower, the partial elliptical pattern is more pronounced for PS3 than for PS6 as seen in Figure 7. It was also found that the ring flip of 180° in PS n has a rather narrow angular distribution. The same technique has been used to study molecular dynamics in glass-forming discotic liquid crystals.⁸

1 INTRODUCTION

In the liquid state, spin relaxation is caused by the random fluctuations of magnetic interactions resulting from Brownian rotational and translational diffusion of molecules, conformational transitions, or solvation effects. These motions act as random time-dependent perturbations, which induce transitions among the spin states and ultimately lead to Boltzmann equilibrium values of macroscopic magnetization vector components, altered by application of the excitation field in relaxation experiments. Random magnetic perturbations are characterized by the equilibrium average $\overline{\Delta}$, the mean-square value $\overline{\Delta^2}$, and the persistence or correlation time τ . It is convenient to express Δ in frequency units rather than in energy units; the strength of the interaction is therefore divided by the Planck constant $\hbar$.

In high-resolution NMR spectroscopy, a fast motional regime, characterized by the condition $(\Delta^2 - \overline{\Delta^2})\tau^2 \ll 1$, often holds. This situation is the simplest to analyze by time-dependent perturbation theories and is generally referred to as the Redfield limit.¹ In this condition, both the longitudinal component of the macroscopic magnetization along the static field $\mathbf{B}_0$, and the transverse component created by the observing field $\mathbf{B}_1$, relax as simple exponentials, with characteristic times T_1 and T_2 , respectively. The theoretical expressions predicted by the theory for T_1^{-1} and T_2^{-1} are very simple and the relaxation times come out to be of the order of $(\Delta^2 - \overline{\Delta^2})\tau$. Thus, if the dominant relaxation mechanism is provided by modulation due to rotational diffusion of an intramolecular interaction described by an axially symmetric second-rank tensor $\mathbf{T}$ with principal components $T_{zz} = T_{\parallel}$ and $T_{xx} = T_{yy} = T_{\perp}$, spin relaxation times of the order of 1 s will result for $\Delta = T_{\parallel} - T_{\perp} = 10^5 \text{ s}^{-1}$ (a value appropriate for the ^{13}C -H spin dipole interaction) and $\tau = 10^{-10} \text{ s}$, corresponding to the rotational correlation time of most liquids under normal conditions.

The motional processes responsible for spin relaxation in liquids are almost invariably interpreted in terms of diffusion models, so that a few comments on the underlying theoretical treatments are in order. A diffusional regime for molecular translations and rotations applies when strong impulsive interactions with the surrounding molecules interrupt the inertial motion of the particle so frequently that a random walk of infinitesimally short steps actually results. To interpret

these dynamic processes, an equation of motion for the test particle can be set up, including a dissipative term in the form of a frictional force. In fact, the resulting equation is the basis of the method for describing molecular motions in fluids known as 'Brownian dynamics'.² (see *Brownian Motion and Correlation Times*.)

Alternatively, a stochastic equation can be derived to interpret the time evolution of the probability distribution function specifying molecular coordinates. The treatment leading to this equation, often referred to as the 'diffusion (or Smoluchowski) equation' when inertial effects are completely quenched, is reported in specialized texts.³ (We reserve the term 'Fokker-Planck equation' for the more general formalism which takes into account translational and angular velocity of the particle, in addition to translational and angular coordinates. According to this description, the diffusional behavior is recovered if velocities are quenched within a time shorter than the decay time for the spatial variables.) The diffusion equation is a differential equation formally similar to a time-dependent Schrödinger equation and it can be solved by similar methods. In fact, after separating the time variable, the solution of the resulting second-order differential equation is reduced to the determination of eigenvalues and eigenvectors of the matrix representation of the diffusion operator on a suitable set of functions. The mathematical details are given elsewhere,^{4,5} so we give here only the relevant physical factors in the diffusion equation. These are:

1. The potential function arising from forces and torques exerted on the test particle, including terms accounting for hindered internal motions.
2. Diffusion coefficients (or, more generally, diffusion tensors) which take into account frictional effects. Diffusion coefficients are determined by the molecular geometry and viscosity of the medium by the Stokes-Einstein relationships.^{6,7}

The general considerations given above hold for both isotropic and anisotropic liquid phases. We will see in the following discussion how the specific nature of the liquid crystal environment may not only alter the characteristics of dynamic processes that occur in normal liquids (e.g. features of rotational and translational diffusion, or static and dynamic parameters of conformational changes), but also introduce novel relaxation mechanisms which are absent in isotropic fluids.

2 EXPERIMENTAL OBSERVABLES

NMR relaxation experiments in liquid crystals can be performed both on the molecules forming the mesophase and on solutes suitably chosen to probe the dynamic properties of the environment. Under normal experimental conditions, fast motional regimes hold, providing well-resolved spectra. Measurements on specific nuclear positions of the molecule can therefore be performed to give data which can then be processed theoretically in order to extract dynamic information. For this reason, ^{13}C (either in natural abundance or chemically enriched) and ^2H (introduced by specific deuteration) are the favored nuclei for use in relaxation experiments on liquid crystals. For ^{13}C and ^2H nuclear spins, the dominant source of spin relaxation is provided by the ^{13}C -H dipole and ^2H quadrupole interactions, respectively. With the very high fields used in modern spectrometers, shielding anisotropies may also have

relevant effects. In all cases, these interactions are described by second-rank Cartesian tensors.

According to the Redfield theory (see *Relaxation Theory: Density Matrix Formulation*), the equations for ^{13}C (under proton decoupling) and ^2H longitudinal relaxation times are

$$1/T_1^{\text{C}} = (\frac{1}{12})[J_0(\omega_{\text{H}} - \omega_{\text{C}}) + 3J_1(\omega_{\text{C}}) + 6J_2(\omega_{\text{H}} + \omega_{\text{C}})] \quad (1)$$

and

$$1/T_1^{\text{D}} = (\frac{1}{4})[J_1(\omega_{\text{D}}) + 4J_2(2\omega_{\text{D}})] \quad (2)$$

where $J_p(\omega)$ are spectral densities, i.e. the Fourier transforms (FTs) of the correlation functions describing the time evolution of the irreducible spherical components⁸ of the second-rank magnetic interactions in a laboratory reference frame. In fact, the magnetic tensor components are defined in a molecular axis system, and therefore appear to vary in time when viewed from the laboratory system, because of molecular tumbling in the liquid. The FTs are calculated at frequency values related to ^1H , ^{13}C , and ^2H resonance frequencies in the experiment. Spectral densities can be expressed in terms of the magnitude of the interactions, and of the time decay of angular functions (Wigner rotation matrix components⁸) which define the molecular orientation with respect to the laboratory fixed reference frame. The FT $j(\omega)$ of an exponential function characterized by time constant τ is

$$j(\omega) = \frac{\tau}{1 + \omega^2\tau^2} \quad (3)$$

Complete dynamic information on a system should be achieved by relaxation experiments capable of providing the various spectral densities at different frequencies. Modern experiments are actually performed at a number of working frequencies.^{9,10} It is also interesting to note that equations (1) and (2) refer to standard experiments of saturation or inversion–recovery of the total longitudinal component of magnetization. In this way, individual spectral densities cannot be obtained directly from experimental data. However, they can be provided by applying appropriate sequences of radiofrequency (rf) pulses to the spin system. Equations for relaxation rates determined by various pulse experiments on a single spin $I = 1$ in ordered phases are reported in Table 3 of Vold¹¹ (see also *Deuteron Relaxation Rates in Liquid Crystalline Samples: Experimental Methods*).

Experiments in liquid crystal phases are performed on samples which are macroscopically oriented by means of magnetic fields, surface effects or electric fields. In some instances, it is also possible to measure the angular dependence of the spectral densities when the axis of preferential alignment of the mesophase (the optical axis, or director) can be rotated away from the magnetic field direction. This can be easily done with uniaxial smectic-A phases. Again, explicit equations for the angular dependence of the spectral densities appropriate for this case may be found in Vold.¹¹

3 DYNAMIC MODELS

In a liquid sample at thermodynamic equilibrium, the dynamic processes which cause thermal motions of the

molecules are defined as random stationary. Although the system is macroscopically in equilibrium, the coordinates specifying the position and orientation of any molecule, here collectively denoted by $\mathbf{x}$, exhibit random walk in time. Any function of these coordinates will behave as a function $f[\mathbf{x}(t)]$ randomly varying in time. If a physical property of the system is related to the function $f(\mathbf{x})$, experimental measurements can be made to determine directly the equilibrium average:

$$\bar{f} = \int d\mathbf{x} f(\mathbf{x})P(\mathbf{x}) \quad (4)$$

thus providing information on equilibrium distribution $P(\mathbf{x})$.

The main result of the stochastic theories is that, for random-stationary processes, knowledge of the random events occurring at the molecular level is entirely contained in a statistical property called the correlation function of $f(\mathbf{x})$:

$$\overline{f^*(t)f(0)} = \iint d\mathbf{x} d\mathbf{x}_0 f^*(\mathbf{x})f(\mathbf{x}_0)P(\mathbf{x}, t; \mathbf{x}_0, 0) \quad (5)$$

where $P(\mathbf{x}, t; \mathbf{x}_0, 0)$ is the joint probability of finding the molecule in $\mathbf{x}_0$ at an arbitrary initial time $t_0 = 0$, and in $\mathbf{x}$ at the later time t . It follows from the properties of the joint probability that this function becomes equal to $P(\mathbf{x})\delta(\mathbf{x} - \mathbf{x}_0)$ at time zero and to the product $P(\mathbf{x})P(\mathbf{x}_0)$ at infinite time, when correlation can no longer exist. Therefore, the correlation function varies between limits $|\bar{f}^2|$ at $t = 0$ and $|\bar{f}|^2$ at $t \rightarrow \infty$. It is often convenient to define the correlation function $g(t)$ for the deviation of $f(t)$ from the equilibrium value $\bar{f}$, thus obtaining

$$g(t) = \overline{f^*(t)f(0)} - |\bar{f}|^2 \quad (6)$$

The mean square value $|\bar{f}^2|$ and average $\bar{f}$ can be calculated from the equilibrium distribution $P(\mathbf{x})$, but the time evolution of the joint probability function requires a mathematical model derived on the basis of a physically reasonable picture, and this is provided by solution of the diffusion equation.

The above considerations may immediately be applied to the problem of reorientational motions, which cause random fluctuations of the intramolecular anisotropic magnetic interactions, and are of particular importance for ^{13}C and ^2H spin relaxation in any liquid phase.

The irreducible spherical components of second-rank tensorial interactions $\mathbf{T}$, expressed in a laboratory frame having the Z axis parallel to the static magnetic field $\mathbf{B}_0$, are given by⁸

$$T_{\text{lab}}^{(2,p)} = \sum_q \mathcal{D}_{pq}^{2*}(\Omega) T_{\text{mol}}^{(2,q)} \quad (7)$$

where $T_{\text{mol}}^{(2,q)}$ are the components in a molecular frame and $\mathcal{D}_{pq}^{2*}(\Omega)$ are Wigner rotation matrix elements carrying the transformation from the laboratory system (X, Y, Z) to the molecular frame (x, y, z), described by the set of Euler angles $\Omega \equiv (\alpha, \beta, \gamma)$. The time dependence of the quantities $T_{\text{lab}}^{(2,p)}$ is contained in that of the Euler angles Ω , which change randomly in time as a consequence of rotational motions. The effective perturbation induced by modulation of the $\mathbf{T}$

tensor components is determined by the deviation from the equilibrium value:

$$\delta T_{\text{lab}}^{(2,p)}[\Omega(t)] = \sum_q \{ \mathcal{D}_{pq}^{2*}[\Omega(t)] - \overline{\mathcal{D}_{pq}^{2*}} \} T_{\text{mol}}^{(2,q)} \quad (8)$$

Of special interest, therefore, are the autocorrelation functions $g_{pq}(t)$ of the Wigner components $\mathcal{D}_{pq}^{2*}(\Omega)$, defined as

$$g_{pq}(t) = \overline{\mathcal{D}_{pq}^{2*}(t) \mathcal{D}_{pq}^2(0)} - |\overline{\mathcal{D}_{pq}^2}|^2 \quad (9)$$

the overbar now denoting an average over the orientational degrees of freedom. The time behavior of the correlation functions $g_{pq}(t)$ is determined by the reorientational process undergone by the molecules, and the thermal averages $\overline{\mathcal{D}_{pq}^2}$ are determined by the nature of the liquid phase.

The spectral densities $J_p(\omega)$ which appear in the equations for the spin relaxation rates are

$$\begin{aligned} J_p(\omega) &= \frac{1}{2} \int_{-\infty}^{\infty} dt e^{-i\omega t} \overline{\delta T_{\text{lab}}^{(2,p)*}(t) \delta T_{\text{lab}}^{(2,p)}(0)} \\ &= \sum_q |\overline{T_{\text{mol}}^{(2,q)}}|^2 j_{pq}(\omega) \end{aligned} \quad (10)$$

where $j_{pq}(\omega)$ are the FTs of the correlation functions $g_{pq}(t)$.

In the case of molecules with internal degrees of freedom, the additional transformation from a fixed molecular frame to a reference system located in each molecular moiety must be considered explicitly. For a tensorial interaction located in the i th unit, equation (7) is rewritten as

$$T_{i,\text{lab}}^{(2,p)} = \sum_{q,n} \mathcal{D}_{pn}^{2*}(\Omega) \mathcal{D}_{nq}^{2*}(\Omega_i) T_i^{(2,q)} \quad (11)$$

The complex expressions resulting for correlation functions and spectral densities are given by Ferrarini et al.^{12,13}

3.1 Rotational Diffusion

In isotropic media, i.e. in the case of a spherically symmetric orientational distribution, it follows from the orthogonality properties of the Wigner functions that

$$\overline{\mathcal{D}_{pq}^2} = 0, \quad |\overline{\mathcal{D}_{pq}^2}|^2 = \frac{1}{5} \quad (12)$$

and the solution of the diffusion equation for axially symmetric molecules characterized by the principal values $D_{\parallel}$ and $D_{\perp}$ of the diffusion tensor gives

$$g_{pq}(t) = \left(\frac{1}{5}\right) \exp(-t/\tau_{pq}) \quad (13)$$

$$1/\tau_{pq} = 6D_{\perp} + (D_{\parallel} - D_{\perp})q^2 \quad (14)$$

Since the orientational correlation time in equation (14) is independent of the index p , the spectral densities $J_p(\omega)$ all turn out to be identical.

In ordered phases, as a consequence of anisotropic interactions with the environment, the molecules are subjected to an effective orientational potential $U(\Omega)$ which, unlike the

isotropic case, determines the nonuniform equilibrium distribution of orientations.

As the diffusion model is appropriate for describing the rotational dynamics of molecules in a liquid of normal density and viscosity, it is also suitable for use for liquid crystals. However, the motion in this case is better termed ‘anisotropic’ rotational diffusion, because of the orientational torques exerted on the molecules.

In nematics, rod-like or disk-like molecules tend to orient the symmetry axis to the director, giving rise to calamitic or discotic nematic phases, respectively. The condition of axial symmetry for the phase implies free rotations around the laboratory Z axis, and therefore $\overline{\mathcal{D}_{pq}^2}$ must be zero for $p \neq 0$. Nematic phases are generally expected to be uniaxial, although biaxiality cannot in principle be excluded. If the molecules themselves are assumed to be uniaxial, rotations about the molecular z axis are unhindered and only terms with $q = 0$ remain. For uniaxial molecules in uniaxial phases, the only order parameter directly measured by NMR is $\overline{\mathcal{D}_{00}^2}$, which coincides with the Legendre polynomial $\overline{P}_2$.⁸ The simple Maier–Saupe form

$$U(\beta)/k_B T = -\lambda P_2(\cos \beta) \quad (15)$$

is appropriate for this particular case, β denoting the angle between the director and the molecular symmetry axis.

The potential of the mean torque acting in nematics has two important effects on the efficiency of rotational motions as a source of spin relaxation. First, the magnitude of time-dependent perturbation is reduced with respect to the isotropic case, as the angular functions $\mathcal{D}_{pq}^{2*}(\Omega)$ average now to non-zero values. Thermal averages $\overline{\mathcal{D}_{pq}^2}$ are called ‘order parameters’, because they measure the anisotropy of the orientational distribution. A second consequence of the orientational potential is to alter the features of rotational motion. Since the particles are preferentially oriented with the symmetry axis (assuming a uniaxially symmetric molecule) parallel to the director, motions can be roughly separated into fast fluctuations about the preferred orientation (with the characteristic frequencies expected to increase with the strength of the orienting field, according to the simple picture of motions in a potential well), essentially free rotations about the symmetry axis, and flippings of the long axis, which, being hindered by the orienting potential, become slower with increasing ordering. The latter motion, however, is a very important relaxation mechanism for vectorial properties, e.g. dielectric relaxation, but it is ineffective for second-rank tensorial properties. The decay of correlation functions $g_{pq}(t)$ can be calculated by solving a diffusion equation for the rotational degrees of freedom, in which the effect of the orienting potential is included.^{4,5} The full solution of the diffusion equation requires expansion on the basis of the Wigner functions $\mathcal{D}_{pq}^j(\Omega)$, which are eigensolutions of the diffusional problem for the isotropic case. Correlation functions $g_{pq}(t)$ can, in most cases, be approximated by single exponentials:

$$g_{pq}(t) = C_{pq} \exp(-\alpha_{pq} t) \quad (16)$$

with the preexponential factors C_{pq} and decay rate constants α_{pq} now being dependent on the order parameters $\overline{P}_2$ and

$\overline{P}_4$, in addition to the diffusion coefficients $D_\perp$ and $D_\parallel$. Particularly simple expressions are obtained by an asymptotic solution of the diffusion problem for very highly ordered systems; these are reported in Table 2 of Chap. 18 of Nordio and Segre⁴ in terms of the parameter $\delta = 1 - \overline{P}_2$, which is a measure of the deviation from perfect alignment. In the limiting case of very high ordering, the only important motion is free rotation about the molecular symmetry axis, the other motions being too rapid to produce any effective spin relaxation.

The considerations given here hold whenever uniaxial orientational order is present, such as in nematic and smectic-A phases. However, they are essentially correct also for cholesteric and smectic-C phases, because a uniaxial environment is experienced at the molecular level.

3.2 Rototranslational Couplings

In phases where both spatial and orientational order are set up, a reorientational process, which is peculiar to liquid crystal phases with spatial inhomogeneity and cannot occur in normal liquids, may result from the translational motions. We consider here the cases of smectic and cholesteric phases. In the former case, elongated molecules tend not only to orient parallel to each other, but also to organize themselves in parallel planes. In uniaxial smectic-A phases, the anisotropic potential acting on a rod-like molecule depends both on the spatial coordinate Z along the director, perpendicular to the smectic layers, and the angle β formed by the director and the molecular axis.^{5,14} Because of the particular form of the potential, usually referred to as the ‘McMillan potential’,^{15,16} the translational and rotational motions of the test molecule are coupled. Physically, a molecule traveling along the Z direction perpendicular to the smectic planes will be subjected to different orientational forces, and therefore the average value of any orientation-dependent interaction will be modulated by the translational motion. In fact, we expect that probe molecules in typical smectic systems are more oriented when surrounded by aromatic cores than when surrounded by aliphatic tails.

Modulation of intramolecular magnetic interactions by translational motion, in addition to that resulting from rotational motion, gives rise to a mechanism reminiscent of scalar relaxation of the first kind,¹⁷ and ultimately produces similar effects. A simple interpretation of this relaxation mechanism can be given in the following way. The translational motion of the molecules is strongly anisotropic, with free diffusion within layers, and hindered diffusion across them. Translations parallel to the layers do not cause spin relaxation, because the orientational order is essentially constant. Spin relaxation results, of course, from anisotropic rotational diffusion, as in nematics. Translations perpendicular to the layers, which explore regions of a different order, are hindered by the anisotropic potential, and could be described by a diffusion equation including the McMillan potential. However, this motion can be visualized as an activated random jump process, with a correlation time given by the mean time required for the molecule to travel across layers of spacing d . The correlation time for the jump process is d^2/D_T , where D_T is the diffusion coefficient for translations perpendicular to the smectic planes. The contribution to the spin-relaxation time is proportional to

$$(\overline{P}_{2\max} - \overline{P}_{2\min})^2 (d^2/D_T) \quad (17)$$

where $\overline{P}_{2\max} - \overline{P}_{2\min}$ is the range of order parameters along Z .

In cholesteric phases too, a novel relaxation mechanism may occur, in addition to those already present in nematics, as a consequence of coupling between rotations and translations.

A simple picture of a single-domain cholesteric phase is that of a nematic in which the director moves along a helical structure, the axis of which is always perpendicular to the director itself. It follows that translation along the helical axis induces rotation of a rod-like molecule, so as to keep the long molecular axis parallel to the director. This motion gives rise to an important contribution to spin relaxation¹⁸ by modulating the residual magnetic anisotropies left by local ordering. The correlation time for this process is the mean time required for the molecule to undergo angular displacement of the director by one radian; this time is of the order of $(p^2/4\pi^2 D_T)$, where p is the helical pitch and D_T the diffusion coefficient for translations perpendicular to the director.

3.3 Internal Motions

The rigid rotor model is only a rough approximation for the dynamics of mesogenic molecules. Actually, molecular flexibility appears to be an important requirement for the achievement of mesomorphic states. Thus, thermotropic liquid crystals are generally made up of aromatic groups linked to flexible chains. The length and the chemical structure of the chains are important in determining their transitional properties and the nature of their mesophases. Very mobile units also characterize the lyotropics, which are water dispersions of molecules with a polar headgroup attached to long aliphatic tails. These species can be organized into structures in which regions with different characteristics can be distinguished: strong interactions of an electrostatic nature maintain the polar headgroups in hydrophilic layers separate from the hydrophobic domains of the alkyl chains. At appropriate temperatures and water concentrations, these systems may undergo transition to liquid crystal phases of different kinds, with the common feature that the chains are well aligned despite the high fluidity of the phase.

The NMR relaxation technique on specifically deuterated molecules was recognized early on as an essential tool in monitoring chain mobility, so that a large amount of experimental data is available. The timescales characterizing bond rotations depend on the specific molecule, but in most cases they range between 10^{-10} and 10^{-8} s. This means that internal motion must be an effective NMR relaxation mechanism, competing with the overall rotation of the molecule.

In the case of mesogenic molecules having a number of torsional degrees of freedom, collectively denoted by φ , the total potential undergone in the oriented phase is

$$U(\Omega, \varphi) = U^{\text{tors}}(\varphi) + U^{\text{or}}(\Omega, \varphi) \quad (18)$$

where $U^{\text{tors}}(\varphi)$ represents the torsional potential, and $U^{\text{or}}(\Omega, \varphi)$ the orientational contribution, which is now expected to depend upon the conformation assumed by the molecule.¹⁹

A multidimensional diffusion equation for both the orientational and the torsional degrees of freedom must be solved

in general but, under the hypothesis that internal and overall motions are decoupled, the two dynamic problems can be treated separately. Molecular reorientations are described by the diffusion model appropriate for uniaxial phases. In an analogous way, the conformational dynamics can be analyzed by solving a diffusion equation for the torsional variables. However, this procedure becomes impracticable when the number of internal degrees of freedom is greater than 3 or 4. An alternative method is based on the consideration that bond rotations are generally strongly hindered by intramolecular interactions, so that the internal potential has deep wells corresponding to a limited number of conformations. This is equivalent to assuming the so-called 'rotational isomeric state (RIS) approximation'.²⁰ It is therefore possible to resort to a kinetic description in terms of a master equation, for the random walk between stable conformers. This master equation can be set up phenomenologically, or be rigorously derived by asymptotic expansion of the diffusion equation in the potential minima.^{21,12} The following equation is obtained for the time evolution of $P_J(t)$, the J th conformer population:

$$\partial P_J(t)/\partial t = - \sum_{J'} W_{JJ'} P_{J'}(t) \quad (19)$$

where $W_{JJ'}$ is the rate constant for the $J' \rightarrow J$ transition. It is calculated by generalizing to the multidimensional case the Kramers result for barrier crossing in an overdamped regime.²² For the simple case of a single degree of freedom, as in the biphenyl molecule in which rotation about the phenyl-phenyl bond is hindered,²³ the rate constant k for a conformational jump is given by

$$k = (k_B T / 2\pi\xi) \omega_m \omega_M \exp \left\{ - \frac{\Delta E}{k_B T} \right\} \quad (20)$$

where ΔE is the barrier height, ξ is the friction exerted by the viscous medium, and ω_m and ω_M are the square roots of the potential curvature along the torsional coordinate, corresponding to the starting minimum and the top of the barrier, respectively.

The structure of the master equation and the expression of the transition rate remain essentially the same in isotropic or anisotropic liquids, but the presence of the orienting potential has a twofold effect:²⁴

1. A purely static effect, consisting in changes in the statistical weights of the various conformations. In calamitic nematics, the most elongated conformers can be more easily accommodated, and they are therefore stabilized at the expense of the most folded ones.
2. A dynamic effect, due to changes in the potential profile along the path of the conformational transitions, which modify the rates of such processes by altering the curvatures and activation energies.

Let us now consider mesogenic molecules formed by an elongated core and an aliphatic chain, such as those belonging to the alkylcyanobiphenyl series.²⁵ Conformational motions cause fast reorientations of the chain segments about the all-*trans* axis, and the whole molecule undergoes anisotropic rotational diffusion. Because of the inequivalence of the conformational sites, isomerization processes alone do not allow the chain segments to be isotropically distributed in space, and so a residual order with respect to the molecular

frame is left, even in isotropic phases. The liquid crystal environment enhances the segmental order by aligning the molecular axes. If there is a timescale separation between the conformational and the overall motions, two distinct processes contributing to spin relaxation can be easily identified. Fast internal motions partially average the interaction tensors located on the various molecular segments, at rates determined by the isomerization frequencies. The partially averaged magnetic tensors are then modulated by the slow anisotropic diffusion. The same conclusions apply to the case of chains anchored to surfaces and undergoing internal and wobbling motions, and thus this can be used as a model system for studies on micelles and membranes.¹³

For illustrative purposes, we report some results obtained for a model 12-bond chain with a fixed end. Each segment of the chain can exist in one of the three states called *gauche*₊ (g_+), *trans*, and *gauche*₋ (g_-). According to the RIS approximation,²⁰ 531 441 different conformers are possible for this system, but only about 257 000 are physically significant, the others being rejected for steric reasons. In an isotropic liquid, the statistical weight of any conformer is never larger than 0.001. Calculations for a liquid crystalline phase of intermediate ordering show that less than 40 conformers have a global statistical weight greater than 10%. These conformers obviously include the all-*trans* configuration, the others having a single *gauche* state at chain positions not far from the free end (a *gauche* state close to the headgroup would dramatically perturb the ordered environment), and the so-called kinks, i.e. conformers with $g_{\pm} t g_{\pm}$ sequences. In all these cases an approximately cylindrical molecular shape is retained. Figure 1 shows the order parameter for the C-H (or C-D) bond and the *gauche* $\rightarrow$ *trans* isomerization rate at each chain segment of the 12-bond chain, in the isotropic and the ordered phases. The anisotropic environment significantly increases the transition rates, and dramatically changes the order parameters. Modulation of the local ordering by slow wobbling motion of the chain axis may become the most relevant mechanism for spin relaxation in the liquid crystalline phase.

3.4 Translational Diffusion and Director Fluctuations

In principle, other kinds of motion, in addition to those described so far, may operate as relaxation mechanisms in

Figure 1 Order parameters and *gauche* $\rightarrow$ *trans* isomerization rates at the various segments of a substrate-supported 12-bond chain, in the isotropic (open symbols) and nematic (filled symbols) phase

liquid crystals. Since rotational diffusion and internal motion are dominant mechanisms for ^{13}C and ^2H spin probes at the high working frequency of standard spectrometers, they will be mentioned only briefly here.

One motional process common to all liquids is translational diffusion. This motion modulates intermolecular dipole–dipole interactions, and efficient spin relaxation results for proton nuclei, because of the abundance of hydrogen atoms in organic molecules. In the case of deuterated compounds, dipole interactions are reduced and intramolecular interactions remain, in practice, the only source of relaxation.

Another interesting process, which is specific to liquid crystal phases, results from elastic deformations of the ordered structures generated by collective thermal motions, which give rise to spontaneous alignment fluctuations. This process is responsible for the scattering of visible light, which in turn causes the turbid appearance of nematics. It also affects the spin relaxation, since it modulates the director orientation in the magnetic field. The corresponding spectral densities display characteristic frequency dependences. Director fluctuations may become the dominant relaxation mechanism at low-frequency regimes, but are relatively unimportant in high-field experiments.

1 INTRODUCTION

Metal ions play a vital role in a large number of biological processes. For this reason, there is widespread interest in NMR of the spin- $\frac{3}{2}$ nuclei ^7Li , ^{23}Na , ^{39}K , and ^{87}Rb , the spin- $\frac{5}{2}$ nuclei ^{25}Mg and ^{85}Rb , and the spin- $\frac{7}{2}$ nuclei ^{43}Ca and ^{133}Cs . In particular, ^{23}Na is one of the most widely studied of all quadrupolar nuclei, especially in vivo. Even in the most heterogeneous biological tissues, however, the NMR spectra of these metal ions usually exhibit only a single resonance at a chemical shift that is characteristic of the aqueous ion. This apparent lack of structure in the spectra is compensated for by the wealth of information about the environment of the ions yielded by the spin relaxation parameters.

It has long been known that both the transverse and longitudinal relaxation of spin $S \geq \frac{3}{2}$ nuclei are multiexponential if the extreme-narrowing condition is not fulfilled.¹ For example, the transverse relaxation of spin- $\frac{3}{2}$ nuclei is described by two distinct relaxation rates, $R_f^{(1)}$ and $R_s^{(1)}$ [the superscript (1) denotes relaxation of single quantum coherences, $p = \pm 1$], if the product of the Larmor frequency ω_0 and correlation time τ_c is unity or greater, $\omega_0\tau_c \gtrsim 1$. As a result of this biexponential relaxation, the NMR spectrum of slowly tumbling spin- $\frac{3}{2}$ nuclei is a superposition of two Lorentzian lines with full widths (in Hz) at halfheight of $R_f^{(1)}/\pi$ and $R_s^{(1)}/\pi$. Figure 1 shows the normal free induction decay and the corresponding spectrum of sodium ions in an agarose gel. The ^{23}Na lineshape can be seen to be bi-Lorentzian, with 60% of the total intensity in the broader component and 40% in the narrower component. Full analysis of the spectrum of a spin- $\frac{3}{2}$ nucleus requires measurement of both the fast, $R_f^{(1)}$, and slow,

Figure 1 Magnitude mode free induction decay (a) and ^{23}Na spectrum (b) of 2 M NaCl in an agarose gel. Acquisition parameters: 2500 Hz spectral width, 48 transients coadded, 105.8 MHz Larmor frequency, 256 points in (a) zero filled to 1024 in (b)

$R_s^{(1)}$, transverse relaxation rates. This is a difficult task, especially if (a) the two relaxation rates are very similar or (b) the relaxation rate $R_f^{(1)}$ is so fast that the broader of the two lines cannot be observed.

In 1986, both Pekar and Leigh² and Jaccard et al.³ showed that multiple quantum coherences could be excited in isolated spin $S \geq \frac{3}{2}$ nuclei in liquids if, but only if, their relaxation was multiexponential. This discovery helped overturn the orthodox view that excitation of multiple quantum coherence required the presence of splittings due to scalar, dipolar, or quadrupolar couplings, and so could not be achieved in a spectrum that consisted of only a single resonance. The aim of this article is to show how multiple quantum NMR is currently being used to measure the relaxation parameters of spin $S \geq \frac{3}{2}$ nuclei in liquid environments. This article will concentrate on spin- $\frac{3}{2}$ nuclei, while multiple quantum NMR of the much less important spin- $\frac{5}{2}$ and spin- $\frac{7}{2}$ nuclei will be mentioned briefly in Section 7.

2 TENSOR OPERATOR DESCRIPTION OF SPIN- $\frac{3}{2}$ QUADRUPOLAR RELAXATION

Jaccard et al.³ have shown that a tensor operator description of multiexponential quadrupolar relaxation is particularly convenient for discussing multiple quantum NMR experiments. In this formulation, the density operator $\sigma(t)$ is expanded as a linear combination of tensor operators:

$$\sigma(t) = \sum_{l=0}^{2S} \sum_{p=-l}^l b_{l,p}(t) T_{l,p} \quad (1)$$

where $T_{l,p}$ is an irreducible spherical tensor operator of rank l and order p . These two concepts have clear meanings in this usage. For example, an operator $T_{1,-1}$ represents an in-phase coherence of order $p = -1$ (i.e., one of the two components of in-phase single quantum coherence), $T_{3,+1}$ represents a doubly

antiphase coherence of order $p = +1$, $T_{3,-2}$ represents a singly antiphase coherence of order $p = -2$ (i.e., a singly antiphase double quantum coherence), and so on. The fact that the rank and coherence order of each term in the expansion of equation (1) are readily identifiable is a major asset in the description of multiple quantum NMR experiments.

A 90°_y pulse applied to a system of spin- $\frac{3}{2}$ nuclei at thermal equilibrium creates in-phase single quantum coherence. If a number of uninteresting constants are ignored, this initial state can be written in tensor form as

$$\sigma(t=0) = T_{1,-1} - T_{1,+1} \quad (2)$$

Jaccard et al.³ have shown that if the time evolution of the density operator occurs solely as a result of biexponential transverse relaxation then the new density operator $\sigma(t)$ is given in tensor operator form by

$$\sigma(t) = f_{11}^{(1)}(t)(T_{1,-1} - T_{1,+1}) + f_{31}^{(1)}(t)(T_{3,-1} - T_{3,+1}) \quad (3)$$

where

$$f_{11}^{(1)}(t) = \frac{1}{5}[3 \exp(-R_f^{(1)}t) + 2 \exp(-R_s^{(1)}t)] \quad (4a)$$

$$f_{31}^{(1)}(t) = \frac{1}{5}\sqrt{6}[\exp(-R_f^{(1)}t) - \exp(-R_s^{(1)}t)] \quad (4b)$$

For pure quadrupolar relaxation in the absence of exchange, the fast and slow transverse relaxation rates can be calculated as

$$R_f^{(1)} = C(J_0 + J_1) \quad (5a)$$

$$R_s^{(1)} = C(J_1 + J_2) \quad (5b)$$

where the spectral densities J_n and the constant C are given by

$$J_n = \frac{2\tau_c}{1 + n^2\omega_0^2\tau_c^2} \quad (6)$$

$$C = \frac{1}{40}(e^2qQ/\hbar)^2(1 + \frac{1}{3}\eta^2) \quad (7)$$

In the extreme-narrowing limit, $\omega_0\tau_c \ll 1$, the two relaxation rates are equal, $R_f^{(1)} = R_s^{(1)} = 4C\tau_c$; hence, the function $f_{31}^{(1)}(t)$ is zero at all times, and spin- $\frac{3}{2}$ transverse relaxation is monoexponential. However, when the ions are tumbling slowly, $\omega_0\tau_c \gtrsim 1$, the two rates are unequal, with $R_f^{(1)} > R_s^{(1)}$, and both the biexponential functions $f_{11}^{(1)}(t)$ and $f_{31}^{(1)}(t)$ are needed for a full description of transverse relaxation.

The function $f_{11}^{(1)}(t)$ in equations (3), (4a), and (4b) describes the biexponential decay of in-phase single quantum coherence, $T_{1,\pm 1}$, with the two components having relative intensities of 60% and 40%. As mentioned in Section 1, this behavior has been known for a long time, and the tensor operator description has here revealed nothing new. Equations (3), (4a), and (4b) also show, however, the biexponential growth and decay of doubly antiphase single quantum coherence, $T_{3,\pm 1}$, according to the function $f_{31}^{(1)}(t)$. Only coherences described by the tensor operator $T_{1,-1}$ give rise to magnetization that is observable as a free induction decay, so these third-rank single quantum coherences cannot

be detected directly.³ It will be shown in the next section, however, that the function $f_{31}^{(1)}(t)$ can be measured using multiple quantum filtration.

The tensor operator description of spin- $\frac{3}{2}$ longitudinal relaxation is broadly similar to that of transverse relaxation.³ If a 180° pulse is applied to a system of spin- $\frac{3}{2}$ nuclei at thermal equilibrium, the resulting deviation from thermal equilibrium can be written in tensor operator form [normalized to equation (2)] as

$$\sigma(t=0) - \sigma^{\text{eq}} = -2\sqrt{2}T_{1,0} \quad (8)$$

If biexponential longitudinal relaxation occurs for a time t , then the new density operator $\sigma(t)$ is given by

$$\sigma(t) - \sigma^{\text{eq}} = -2\sqrt{2}[T_{1,0}f_{11}^{(0)}(t) + T_{3,0}f_{31}^{(0)}(t)] \quad (9)$$

where

$$f_{11}^{(0)}(t) = \frac{1}{5}[\exp(-R_f^{(0)}t) + 4 \exp(-R_s^{(0)}t)] \quad (10a)$$

$$f_{31}^{(0)}(t) = \frac{2}{5}[\exp(-R_f^{(0)}t) - \exp(-R_s^{(0)}t)] \quad (10b)$$

The fast and slow longitudinal relaxation rates for pure quadrupolar relaxation are given by [the superscript (0) denotes relaxation of spin populations, $p = 0$]

$$R_f^{(0)} = 2CJ_1 \quad (11a)$$

$$R_s^{(0)} = 2CJ_2 \quad (11b)$$

As with transverse relaxation, equations (9)–(11b) show that in the extreme-narrowing limit, $R_f^{(0)} = R_s^{(0)} = 4C\tau_c$, so that longitudinal relaxation is monoexponential. Outside this limit, the relaxation is again biexponential, with $R_f^{(0)} > R_s^{(0)}$. Multiple quantum filtration experiments that allow the function $f_{31}^{(0)}(t)$ to be measured will be discussed in the next section.

3 MULTIPLE QUANTUM FILTRATION EXPERIMENTS FOR SPIN- $\frac{3}{2}$ NUCLEI

A tensor operator $T_{l,p}$ transforms under a radiofrequency pulse of flip angle β and phase ϕ according to

$$T_{l,p} \xrightarrow{\beta(\hat{I}_y \cos \phi - \hat{I}_x \sin \phi)} \sum_{p'=-l}^l T_{l,p'} d_{p',p}^l(\beta) \exp(-i\Delta p \phi) \quad (12)$$

where p' is the new coherence order, and $\Delta p = p' - p$ is the change in coherence order under the pulse.³ The amplitude of the transfer $T_{l,p} \rightarrow T_{l,p'}$ is given by the reduced rotation matrix element $d_{p',p}^l(\beta)$. These elements are defined to be real; hence, the phase ϕ represents a positive excursion with respect to the rotating frame y axis (i.e., $\phi = 0^\circ$ for a y pulse, $\phi = 90^\circ$ for a $-x$ pulse, and so on).

The important feature revealed by equation (12) is that a pulse cannot change the rank l of a tensor operator (or the coherence it represents), but will, in general, produce operators of all possible coherence orders p . Thus, while the $T_{1,\pm 1}$ terms

in equation (3) cannot be transformed by a pulse into multiple quantum coherences ($|p| \geq 2$), the $T_{3,\pm 1}$ terms that appear as a result of biexponential spin- $\frac{3}{2}$ transverse relaxation can be transformed into triple quantum coherences, $T_{3,\pm 3}$, and antiphase double quantum coherences, $T_{3,\pm 2}$. Therefore, it is the appearance of the third-rank terms in equations (3) and (9) that makes the excitation of multiple quantum coherence possible.

Figure 2 shows two pulse sequences for multiple quantum filtration of spin- $\frac{3}{2}$ nuclei and their corresponding coherence pathway diagrams.⁴ The standard multiple quantum filtration experiment in Figure 2(a) allows the transverse relaxation function $f_{31}^{(1)}(t)$ to be measured.^{2,3} At the end of the τ_e evolution interval, both $T_{1,\pm 1}$ and $T_{3,\pm 1}$ operators will be present as result of biexponential transverse relaxation (the 180° pulse merely refocuses any offsets). Depending on its phase ϕ' , the $\beta = 90^\circ$ pulse then converts the $T_{3,\pm 1}$ coherences into either double ($T_{3,\pm 2}$) or triple ($T_{3,\pm 3}$) quantum coherences, which can be selected by an appropriate phase cycling of the receiver and the pulse phase ϕ . The final $\beta' = 90^\circ$ pulse then reconverts these multiple quantum coherences into a single quantum coherence, $T_{3,\pm 1}$, at the start of acquisition of the free induction decay. As mentioned

above, this third-rank single quantum coherence is not directly observable. However, further biexponential transverse relaxation during the free induction decay will convert the $T_{3,-1}$ coherence into an observable $T_{1,-1}$ coherence. The function that describes this conversion can be written as $f_{13}^{(1)}(t)$ in analogy to equation (3), and it is easily shown that $f_{13}^{(1)}(t) = f_{31}^{(1)}(t)$. Using equations (3) and (12), the observable components of the density operators produced by the double and triple quantum filters in Figure 2(a) can be calculated as³

$$\sigma^{\text{DQF}}(t_2) = \frac{10}{16} T_{1,-1} f_{31}^{(1)}(\tau_e) f_{31}^{(1)}(t_2) \cos 2\phi \quad (13a)$$

$$\sigma^{\text{TQF}}(t_2) = \frac{15}{16} T_{1,-1} f_{31}^{(1)}(\tau_e) f_{31}^{(1)}(t_2) i \sin 3\phi \quad (13b)$$

where evolution solely as a result of transverse relaxation has been assumed. The dependence on the pulse phase ϕ in equations (13a) and (13b) is the basis for selection of these components by phase cycling. Note that either double or triple quantum filtration can be used to measure the function $f_{31}^{(1)}(t)$, either as a function of the evolution interval τ_e or in ‘real time’ as the envelope of the free induction decay. The only difference between the results of the two experiments is that the spin- $\frac{3}{2}$ triple quantum filter is 50% more sensitive than the double quantum filter.⁵

The pulse sequence in Figure 2(b) can be viewed as a multiple quantum filtered inversion–recovery experiment, and allows the longitudinal relaxation function $f_{31}^{(0)}(t)$ to be measured.³ Again, either double (with $\beta = 54.7^\circ$) or triple (with $\beta = 90^\circ$) quantum filtration are possible. Using equations (9) and (12), the observable component of the density operator for each alternative can be written as

$$\sigma^{\text{DQF}}(t_2) = \frac{5}{6} \sqrt{2} T_{1,-1} f_{31}^{(0)}(\tau_e) f_{13}^{(1)}(t_2) \cos 2\phi \quad (14a)$$

$$\sigma^{\text{TQF}}(t_2) = \frac{5}{8} \sqrt{6} T_{1,-1} f_{31}^{(0)}(\tau_e) f_{13}^{(1)}(t_2) i \sin 3\phi. \quad (14b)$$

Thus, either double or triple quantum filtration can be used to measure $f_{31}^{(0)}(t)$ as a function of the evolution interval τ_e . The envelope of the free induction decay is again described by the transverse biexponential function $f_{31}^{(1)}(t)$.

4 MEASUREMENT OF SPIN- $\frac{3}{2}$ RELAXATION PARAMETERS

The free induction decay produced by the triple quantum filter of Figure 2(a) from sodium ions in an agarose gel is shown in Figure 3(a). As predicted, the envelope of the free induction decay is the difference of two exponentials, and corresponds to the function $f_{31}^{(1)}(t_2)$. Fourier transformation of this free induction decay in the normal way yields the triple quantum filtered ^{23}Na spectrum in Figure 3(b). This spectrum corresponds to a function $F_{31}^{(1)}(\omega)$, the Fourier transform of $f_{31}^{(1)}(t)$, and is the difference of two Lorentzian lines with widths $R_f^{(1)}/\pi$ and $R_s^{(1)}/\pi$.

The experimental results in Figure 3(a) and (b) are described by exactly the same two relaxation rates, $R_f^{(1)}$ and $R_s^{(1)}$, as the results in Figure 1. However, the use of multiple quantum filtration has conferred a number of advantages. First, the very fact that a multiple quantum filtered spectrum can be recorded

Figure 2 Pulse sequences and coherence pathway diagrams for multiple quantum filtration of spin- $\frac{3}{2}$ nuclei. Sequence (a) is used to study biexponential transverse relaxation, while sequence (b) is used to study longitudinal relaxation. The pulse phase ϕ in (a) and (b) is stepped through the values 0° , 90° , 180° , and 270° for double quantum filtration (dashed coherence pathways), and through 30° , 90° , 150° , 210° , 270° , and 330° for triple quantum filtration (solid pathways), while the receiver phase alternates between 0° and 180° . The pulse phase ϕ' in (a) is 0° for double quantum and 90° for triple quantum filtration. Maximum sensitivity is achieved with flip angles $\beta = \beta' = 90^\circ$, except for the double quantum filtration version of (b), where $\beta = 54.7^\circ$. The interval τ_m is a few microseconds to allow for phase shifting of the pulses, unless multiple quantum relaxation rates are being measured. The double quantum filtration version of (a) can be used selectively to observe spin- $\frac{3}{2}$ nuclei in ordered environments if $\beta = \beta' = 54.7^\circ$.

Figure 3 Magnitude mode free induction decay (a) and ^{23}Na spectrum (b) of 2 M NaCl in an agarose gel recorded with the triple quantum filter of Figure 2(a). The amplitudes of ^{23}Na spectra recorded with the triple quantum filter of Figure 2(a) are plotted in (c) as a function of the evolution interval τ_e (triangles represent 100 amplitudes between $\tau_e = 0$ and 99 ms). Computer fitting (dashed line) of the points in (c) yielded the relaxation rates $R(1)/f = 409 \text{ s}^{-1}$ and $R(1)/s = 30.7 \text{ s}^{-1}$. Similarly, the amplitudes of ^{23}Na spectra recorded with the triple quantum filter of Figure 2(b) are plotted in (d) as a function of τ_e (triangles represent 30 amplitudes between $\tau_e = 0$ and 116 ms). Computer fitting (dashed line) of the points in (c) yielded the relaxation rates $R(0)/f = 38.5 \text{ s}^{-1}$ and $R(0)/s = 29.7 \text{ s}^{-1}$. Acquisition parameters for all spectra: 2500 Hz spectral width, 48 transients co-added, 105.8 MHz Larmor frequency, 256 points acquired and zero filled to 1024

is significant, since it constitutes unambiguous proof that the ^{23}Na nuclei are tumbling outside the extreme-narrowing limit. Second, both the conventional and multiple quantum filtered data are now available for computer fitting, and this should result in increased accuracy. Third, it is believed that, owing to its greater number of turning points, the $F_{31}^{(1)}(\omega)$ lineshape should yield more reliable fittings than the conventional

lineshape $F_{11}^{(1)}(\omega)$, especially when the two relaxation rates are similar. And finally, because the first point of the free induction decay is zero, the multiple quantum filtered spectrum shows less baseline distortion than the conventional spectrum.

The use of multiple quantum filtration is particularly favorable when the broad component of the spin- $\frac{3}{2}$ lineshape cannot be observed because it has relaxed completely in the 'dead time' between the end of the last pulse and the start of data acquisition. Clearly, this 'visibility' problem will be the same in both conventional and multiple quantum filtered spectra. Equations (13a) and (13b) show, however, that the function $f_{31}^{(1)}(t)$ can also be measured by recording the intensity of the filtered spectrum as a function of the evolution interval τ_e . This measurement suffers from no dead time problems, and, in addition, the presence of the 180° pulse means that the effects of B_0 inhomogeneity are refocused. Figure 3(c) shows the experimental function $f_{31}^{(1)}(t)$ measured in this way for the gel sample used previously. The computer fitting of these points yielded the ^{23}Na relaxation rates $R_f^{(1)} = 409 \text{ s}^{-1}$ and $R_s^{(1)} = 30.7 \text{ s}^{-1}$.

The longitudinal relaxation function $f_{31}^{(0)}(t)$ can be measured as a function of the τ_e interval in the experiment of Figure 2(b) in much the same way as the transverse function.³ Figure 3(d) shows a computer fitting of results from the agarose gel that yielded the ^{23}Na relaxation rates $R_f^{(0)} = 38.5 \text{ s}^{-1}$ and $R_s^{(0)} = 29.7 \text{ s}^{-1}$. In general, however, the longitudinal triple quantum filter is much less sensitive and informative than the transverse experiment, and has not attained the same widespread popularity in spin- $\frac{3}{2}$ NMR.

In addition to the methods discussed so far, it is also possible to measure the spin- $\frac{3}{2}$ multiple quantum relaxation rates using a minor modification of the pulse sequence of Figure 2(a).^{3,6} The decays of $T_{3,\pm 2}$ and $T_{3,\pm 3}$ are monoexponential and can be measured as functions of the τ_m interval (previously assumed to be of negligible duration) in the double and triple quantum filtration experiments, respectively. A 180° refocusing pulse can be inserted into the middle of the τ_m interval if required.

A full discussion of the analysis of spin- $\frac{3}{2}$ relaxation rates measured using multiple quantum filtration experiments is beyond the scope of this article, and only a brief summary can be given here. The relaxation rates given in equations (5a), (5b), (11a), and (11b) were derived on the assumption that relaxation is purely quadrupolar and is described by a single correlation time τ_c . In this case, the correlation time τ_c and the constant C can be easily extracted from the ratio of any two of the measured relaxation rates. In systems where rapid chemical exchange is occurring, however, the assumption of a single correlation time is clearly invalid. This applies to spin- $\frac{3}{2}$ ions in agarose gels, in aqueous solutions of proteins, and in both intra- and extracellular environments in cell suspensions and tissues.⁷⁻⁹ In 1972, Bull¹⁰ proposed a two-site exchange model for spin- $\frac{3}{2}$ nuclei in such systems. In this model, an observed relaxation rate is the weighted sum of the relaxation rate of ions bound to macromolecules and of those in free solution, the weights being the probabilities of the ions being found in each environment. The Bull model is attractive, since the free relaxation rates can easily be estimated and the free site probability can be taken as approximately unity. Thus, the bound relaxation rates can be easily derived and then treated according to the single correlation time model. Unfortunately,

in spite of its elegance, the Bull model does not seem to be very successful in explaining the majority of experimental data. If, using the full range of experimental techniques available, the six possible relaxation rates are measured for a spin- $\frac{3}{2}$ nucleus in, say, a protein solution then it is usually found that the value of τ_c calculated by taking the ratio of a pair of relaxation rates can differ by an order of magnitude according to which pair is chosen.^{7,8} For example, using $R_{\text{free}} = 25 \text{ s}^{-1}$, a Bull analysis of the rates $R_f^{(1)}$ and $R_s^{(1)}$ measured in Figure 3(c) yields $\omega_0\tau_c = 9.1$, while the analysis of $R_f^{(0)}$ and $R_s^{(0)}$ measured in Figure 3(d) yields $\omega_0\tau_c = 1.3$. Although the error on the latter figure may be very large because of the closeness of $R_f^{(0)}$ and $R_s^{(0)}$, the failure of the two-site Bull model is clear. Attempts to extend the Bull model to include multisite exchange would seem to be futile, since (a) the number of parameters would soon become too large for any meaningful fitting, and (b) it is unlikely that monovalent metal ions bind in any discrete manner to the majority of macromolecules. In a more promising development, however, Rooney and Springer^{7,8} have successfully fitted ^{23}Na relaxation data from both protein solutions and cell suspensions by using a model that allowed for a continuous distribution of correlation times.

5 DISCRIMINATION OF INTRA- AND EXTRACELLULAR SPIN- $\frac{3}{2}$ NUCLEI

As mentioned in Section 1, the ^{23}Na or ^{39}K NMR spectra of heterogeneous biological tissues or cell suspensions, either in vivo or in vitro, exhibit only a single resonance at a chemical shift characteristic of the aqueous ion. This is unfortunate, since a key aim of such studies is to determine selectively the relaxation parameters of the ions in the individual tissue compartments. One solution to this problem involves the use of lanthanide shift reagents,^{11,12} such as $\text{Dy}(\text{PPP})_2^{7-}$ or TmDOTP^{5-} . These are too large to cross the cell membrane, and so produce a paramagnetic shift of only the extracellular resonance. The main disadvantage of shift reagents is their toxicity. Nevertheless, they have proved popular for in vitro work and have occasionally been used in vivo, although never, of course, for studies on humans.

In 1987, Pekar et al.¹³ suggested that multiple quantum filtration could be used to observe selectively the resonance from intracellular spin- $\frac{3}{2}$ metal ions. The idea was that the intracellular ions would be slowly tumbling and would thus exhibit biexponential transverse relaxation, while the extracellular ions would be in the extreme-narrowing limit. A double or triple quantum filter would, therefore, fail to excite any multiple quantum coherences in the extracellular nuclei, and only signal from the intracellular ions would appear in the spectrum. This technique has proved only a partial success, however, since it has been found that, in general, the extracellular ions also exhibit biexponential relaxation.^{14,15} In spite of this, the relaxation behavior of spin- $\frac{3}{2}$ nuclei does differ widely between the various tissue compartments, and multiple quantum filters have been used to achieve partial discrimination between compartments in situations where shift reagents are not appropriate.

As an example of the degree of discrimination achieved, Figure 4(a) and (b) show the conventional and triple quantum filtered ^{23}Na NMR spectra of packed human red blood

Figure 4 Conventional, (a) and (c), and triple quantum filtered, (b) and (d), ^{23}Na spectra of human red blood cells. Packed cells were used in (a) and (b), and cells suspended in a solution of 50 mM NaCl, 100 mM choline chloride, and 6 mM DyTTHA^{3-} were used in (c) and (d). The pulse sequence of Figure 2(a) was used in (b) and (d). Acquisition parameters: 2500 Hz spectral width, 240 transients coadded for (a) and (c), 2400 transients coadded for (b) and (d), 105.8 MHz Larmor frequency, 128 points acquired and zero filled to 512, 5 ms evolution interval τ_e in (b) and (d). Fresh blood was drawn from the author on the day of the experiments

cells, while Figure 4(c) and (d) show the corresponding spectra of human red blood cells suspended in a solution containing 50 mM NaCl, 100 mM choline chloride, and 6 mM DyTTHA^{3-} . The triple quantum filtered lineshape of the intracellular ions in Figure 4(d) corresponds closely to that of Figure 4(b), while the intensity of the extracellular resonance relative to the intracellular resonance is clearly much reduced in Figure 4(d) compared with Figure 4(c).

6 RESIDUAL SPIN- $\frac{3}{2}$ QUADROPOLAR SPLITTINGS

The discussion in this article of the use of multiple quantum filtration in the study of spin- $\frac{3}{2}$ quadrupolar relaxation has so far assumed that the ions occur in purely isotropic, liquid-type environments; hence, their spectra exhibit no quadrupolar splittings. In 1986, however, Jaccard et al.³ noted that if residual quadrupolar splittings were present but were

not apparent in the lineshape then these would provide an alternative pathway for the excitation of multiple quantum coherence. If, starting from the initial state of equation (2), free precession occurs solely as a result of the residual quadrupolar splitting $2\omega_Q$ for a time t then the new density operator is given by

$$\sigma(t) = g_{11}^{(1)}(t)(T_{1,-1} - T_{1,+1}) + g_{21}^{(1)}(t)(T_{2,-1} + T_{2,+1}) + g_{31}^{(1)}(t)(T_{3,-1} - T_{3,+1}) \quad (15)$$

where

$$g_{11}^{(1)}(t) = \frac{1}{5}(2 + 3 \cos 2\omega_Q t) \quad (16a)$$

$$g_{21}^{(1)}(t) = i\sqrt{\frac{3}{5}} \sin 2\omega_Q t \quad (16b)$$

$$g_{31}^{(1)}(t) = -\frac{1}{5}\sqrt{6}(1 - \cos 2\omega_Q t) \quad (16c)$$

The functions $g_{ij}^{(1)}(t)$ in equations (15)–(16c) describe the evolution of in-phase single quantum coherence, $T_{1,\pm 1}$, into antiphase single quantum coherence, $T_{2,\pm 1}$, and doubly antiphase single quantum coherence, $T_{3,\pm 1}$. The major difference between evolution as a result of biexponential relaxation and residual quadrupolar splittings, therefore, is that only in the latter case do singly antiphase coherences, $T_{2,\pm 1}$, appear.

The appearance of the operator $T_{2,\pm 1}$ as a result of a quadrupolar splitting forms the basis of a method of distinguishing this effect from biexponential relaxation. If the double quantum filter of Figure 2(a) is performed on a system that exhibits a residual quadrupolar splitting then both in-phase double quantum coherence, $T_{2,\pm 2}$, and antiphase double quantum coherence, $T_{3,\pm 2}$, will be selected. This does not achieve the desired discrimination, since $T_{3,\pm 2}$ coherence arising as a result of pure transverse relaxation will also be selected by the filter. Jaccard et al.³ and Eliav et al.¹⁶ have shown, however, that if either or both of the flip angles β or β' in the double quantum filter is set to 54.7° then third-rank coherences are suppressed and only second-rank coherences will appear. Thus, the resulting spectrum will feature only those ^{23}Na nuclei that exhibit a residual quadrupolar splitting. The Jeener–Broekaert experiment can be used to achieve the same result with slightly higher sensitivity.¹⁷

Figure 5(a) shows the double quantum filtered ^{23}Na spectrum (with $\beta = \beta' = 90^\circ$) of the suspension of human red blood cells used in Figure 4(c) and (d). If biexponential relaxation were solely responsible for this spectrum then equations (13a) and (13b) show that these lineshapes would be identical to those in the triple quantum filtered spectrum in Figure 4(d). Clearly, however, both intra- and extracellular lineshapes are very different, and this is because those in Figure 5(a) contain a $T_{2,-1}$ component that has arisen from residual quadrupolar splittings hidden within the linewidth. Figure 5(b) shows the result of using the double quantum filter of Figure 2(a) with $\beta = \beta' = 54.7^\circ$ to record a spectrum arising solely from ^{23}Na nuclei that exhibit residual quadrupolar splittings (presumably those associated with the cell membrane^{18,19}). The lineshapes here consist of antiphase spin- $\frac{3}{2}$ powder patterns, except that, using the same phasing parameters as in Figure 5(a), they appear in dispersive mode.^{16,17}

Figure 5 Double quantum filtered ^{23}Na spectra of the red blood cell suspension used in Figure 4(c) and (d). The experiment of Figure 2(a) was used with $\beta = \beta' = 90^\circ$ (a) and $\beta = \beta' = 54.7^\circ$ (b). Acquisition parameters: 2500 Hz spectral width, 2400 transients coadded, 105.8 MHz Larmor frequency, 128 points acquired and zero filled to 512, 5 ms evolution interval τ_e

7 DISCUSSION AND SUMMARY

This article has concentrated on spin- $\frac{3}{2}$ nuclei. This is inevitable, since nuclei such as ^7Li , ^{39}K , ^{87}Rb , and, in particular, ^{23}Na are studied very frequently, while higher spin nuclei such as ^{25}Mg , ^{43}Ca , ^{85}Rb , and ^{133}Cs have less favorable NMR parameters and are only rarely studied. Multiple quantum filtration has been used, however, in ^{25}Mg NMR of MgCl in bovine albumin solutions.^{20,21} The relaxation of spin- $\frac{5}{2}$ nuclei is triexponential outside the extreme narrowing limit, and is described by transverse and longitudinal functions of the type $f_{11}^{(n)}(t)$, $f_{31}^{(n)}(t)$, and $f_{51}^{(n)}(t)$. Thus, excitation of multiple quantum coherences up to $p = \pm 5$ is possible. The most straightforward method of determining the relaxation parameters of spin- $\frac{5}{2}$ nuclei is probably measurement of the four- and five-quantum relaxation rates in an analogous way to which the double and triple quantum relaxation rates can be measured for spin- $\frac{3}{2}$ nuclei.²¹

In summary, since being introduced only in 1986, multiple quantum filtration studies of quadrupolar relaxation have proved highly rewarding, especially in biological systems. Multiple quantum filters allow the biexponential relaxation of spin- $\frac{3}{2}$ nuclei to be measured with great accuracy, and have also been used to obtain partial discrimination of sodium and potassium ions in the various compartments of tissues and cell suspensions. A relatively new application of multiple quantum filtration has been the selective observation and study of spin- $\frac{3}{2}$ nuclei that exhibit residual quadrupolar splittings as a result of their association with ordered structures in cells and tissues. In addition to the applications discussed here, multiple quantum filters have also been used as a method of reversing contrast in ^{23}Na magnetic resonance imaging^{22–24} and as a method of accurately measuring spin- $\frac{3}{2}$ dynamic shifts.²⁵ It seems likely that interest in all these areas will continue to grow in the next few years.

1 INTRODUCTION TO SUPERCRITICAL FLUIDS

While the existence of the supercritical ‘phase’ has been known for over 150 years it has been only in the last 20 years that the value of supercritical fluids (SCFs) as a medium for extraction, cleaning and synthesis has been recognized. It is now clear that SCF processes are often constrained to very narrow regions of economic feasibility due to the phase behavior of the solute-solvent system. As a result, there needs to be very tight controls over any industrial process employing SCFs. If the process parameters must be more exact, then so does the information required to generate the design parameters, which includes experimental measurements, theories, and the correlations that result in predictability in a given system. In an effort to expand the current understanding of SCFs and their applications, intensive studies are ongoing using nuclear magnetic resonance (NMR). In an effort to further explain the physical chemistry inherent to possible applications of SCFs, a brief introduction is given to this odd and often ignored ‘phase’ of substances. Following that is an introduction to NMR as it pertains to the study of SCF applications.

2 SUPERCRITICAL FLUIDS

2.1 General Properties

The supercritical state is defined by the critical pressure (P_c) and critical temperature (T_c). One of the most common phenomenological definitions describes critical pressure as the pressure above which, regardless of the applied temperature, a liquid cannot be made to boil. In a similar way, the critical temperature can be thought of as the temperature above which, regardless of the applied pressure, a gas cannot be converted into a liquid. Hence, above the critical point there is no longer a phase boundary between the liquid and the vapor. A liquid/vapor phase boundary represents a coexistence line so that material crossing it requires the expenditure of the latent heat of vaporization.

The concept of the supercritical state can be illustrated by a physical example. Consider a closed container of constant

volume. Inside the container we start with some amount of pure liquid. The space above this pure liquid will be filled with pure vapor at the liquid’s equilibrium vapor pressure. Now assume that we begin to heat up this container slowly and uniformly. The density of the liquid will begin to decrease through normal thermal expansion. Meanwhile, the density of the vapor phase begins to increase since more molecules are leaving the liquid to enter the vapor phase. Continued heating results in a further decrease of the liquid density and an increase in the vapor density. Eventually, at some temperature, T_c (and resulting, uniform pressure, P_c), the density of the liquid and vapor phases reach the same value, and the vapor and liquid ‘phases’ have identical compositions and identical densities.

Is this supercritical fluid phase to be considered a liquid or a gas? The answer is that a supercritical fluid reflects properties of both. Table 1 shows relative values of the density, diffusion coefficient, and viscosity for a typical liquid, gas, and supercritical fluid. These values indicate the mass transport properties (i.e., diffusivity) are similar to a gas, while the mechanical properties (viscosity and density) are similar to those of a liquid. This unique combination of properties makes supercritical fluids attractive for use as solvents. The high diffusivity and low viscosity allows the fluid to penetrate easily into matrices which are in the form of loose powders, compacted powders, or even fully cemented pre-forms. Further, the ability of a solvent to dissolve other liquids is, to a first approximation, related to the density of the solvent. The relatively high density of supercritical fluids, relative to gases, increases the useful levels of solubility that may be attained.

2.2 Supercritical CO₂

As a result of the law of corresponding states the physical properties of supercritical CO₂ apply to all fluids in the supercritical state. The critical values of temperature and pressure are unique for each gas/liquid and are determined by the type of intermolecular interactions occurring between

Table 1 Comparison of physico-chemical properties of a typical organic fluid in the liquid, gas, and supercritical fluid state

	Liquid	Supercritical fluid	Gas
Density (g cm ⁻³)	1	0.1–1	10 ⁻³
Viscosity (Pa·s)	10 ⁻³	10 ⁻⁴ –10 ⁻⁵	10 ⁻⁵
Diffusivity (cm ² s ⁻¹)	10 ⁻⁵	10 ⁻³	10 ⁻¹

Table 2 Critical temperature, T_c , and Pressure, P_c , for some common fluids

Fluid	T_c (°C)	P_c (psi)
Neon, Ne	–229	400
Nitrogen, N ₂	–147	492
Argon, Ar	–122	706
Xenon, Xe	17	858
Carbon dioxide, CO ₂	31	1072
Sulfur hexafluoride, SF ₆	46	545
Propane, C ₃ H ₈	97	617
Ammonia, NH ₃	133	1654
Water, H ₂ O	374	3209

the individual molecules. Table 2 gives the critical temperature and pressure of some common fluids. For example, the critical temperature and pressure required to transform water (H_2O) into a supercritical fluid are 374°C and 218 atmospheres. These values are much higher than those for CO_2 because the water molecules exert an attractive force on each other, making the solid and liquid phases particularly stable. CO_2 molecules, on the other hand, have much weaker intermolecular attractive forces. It is important to note that, in the SCF region, attractive forces between molecules are minimized.

In the solid form CO_2 has a high density and a very high viscosity. Similarly, the liquid has a high density and a reasonably high viscosity, and the gas has a low density and low viscosity. Conversely, the supercritical fluid phase has a high density but a relatively low viscosity. The density of supercritical CO_2 can vary over a wide range from gas values, around 0.1 g cm^{-3} , to liquid values of about 2.0 g cm^{-3} . In other words, the density of supercritical CO_2 can be changed by over 2000% simply by varying the temperature and pressure within the supercritical region. A supercritical fluid is by definition both liquid and gas-like, and hence it is compressible. Thus, relatively small changes in temperature and/or pressure can significantly affect the density, as seen in Figure 1.

As the density of the CO_2 becomes more liquid-like, so do the solvent properties of the fluid. To a first approximation, the ability of a supercritical fluid to dissolve other fluids can be related to its density in the supercritical region. When operating in the supercritical region, therefore, both temperature and pressure can be used to vary the density, and therefore, the dissolving power of the fluid. It is this ability to alter the solvent power that makes supercritical CO_2 such an attractive solvent. To make the potential for SCFs even more promising, small additions of other components, called co-solvents or entrainers, often modify the observed phase

equilibria dramatically. Again this special property affords the chemist the opportunity to *tailor* solvents to achieve a variety of goals, either in separations or reactions.

The viscosity of carbon dioxide is observed to change rapidly in the critical region, as is the case also for diffusivity. Even at high pressures of 300–400 atm it is still only about 0.09 centipoise, an order of magnitude below typical organic solvents. Because of these density and viscosity properties, supercritical CO_2 possesses certain other characteristics, which enhance its attractiveness as a solvent. In addition to possessing liquid-like densities over much of the temperature and pressure range of interest to industry, it exhibits the gas-like property of diffusivity with a zero value for the surface tension. These features alter the transport to allow for easy penetration of SCFs into nano-dimensional spaces.

The self-diffusion coefficient for carbon dioxide (which is approximately the same for similar sized molecules diffusing through carbon dioxide) is about one to two orders of magnitude higher than the diffusivities of comparable solutes in typical organic liquids.

2.3 NMR of Supercritical Fluids

The interactions of a nuclear moment with other nuclei and the electrons surrounding it provide a very sensitive site specific probe into the structure and dynamics in the solid, liquid, and gas phase. This work will concern itself with NMR in the supercritical fluid state of carbon dioxide. As mentioned above, these states exhibit properties of both the liquid and the gas phases. Thus, techniques and theory from work in both phases combine in these unique applications. Thorough reviews have been published on the unique information which can be obtained in the gas phase.^{1,2} Other reviews have been published on experimental techniques and applications of high pressure NMR.^{3,4} These reviews were published on or before

Figure 1 Pressure–temperature–density surface of pure CO_2

1991. We will discuss primarily studies published later, with information as it relates specifically to NMR determination of the dynamics and structure in the SCF state.

Although the application of high pressure NMR to simple fluids leads to some interesting additional complications, the information gained from the technique more than justifies its use. The pressure axis provides an additional dimension to the experimental matrix. For a liquid it is commonly known that temperature changes at constant pressure will effect the molecular motion via kinetic energy and molecular average volume collisional arguments. One can separate the effects of density and temperature on the molecular motion only if both the temperature and pressure are controlled variables in the NMR experiment. Increased pressure also allows for the experimental range to expand well above the normal boiling point and into the compressible supercritical fluid regime. Some examples of the usefulness of high pressure NMR will be given.

2.4 Introduction to the Basics of High-pressure NMR

The motions of molecules in liquids is accessible only through a large number of various models that depend upon phenomenological parameters such as the coefficient of rotational diffusion, the frequency of collisions, the time between jumps, etc. Three such theories: the random walk theory of Torrey,⁵ the rotational diffusion theory of Abragam,⁶ and the rotational Brownian motion of McConnell⁷ form the basis upon which most NMR relaxation models in liquids are based. Other methods of studying molecular motion (optical, dielectric, neutron scattering, etc.) can in principal give additional detailed information. However, as a consequence of the many-particle effects present in these methods, the interpretation of the experimental results for liquids is often ambiguous. In NMR, the weak coupling of the spin system with the lattice allows one to focus better on isolated molecular motions to describe relaxation in liquids.⁸ Information on the rotational motion of molecules in liquids of low viscosity, given by NMR, is obtained in the form of the integrals of the time correlation functions, i.e., the correlation times. This section will discuss the effects of dense gas and supercritical fluid states on the correlation times, and what this means to the NMR spectroscopist.

2.5 The Origin of Nuclear Spin Relaxation

Direct time dependant interactions have been shown to cause spin relaxation. However any static interaction can simply be treated as part of the normal spin Hamiltonian, altering the positions and intensities of the spectral lines. For example, a nuclear spin may experience a local magnetic field from the spins of other nuclei moving in its vicinity, from an unpaired electron, or from a variety of other mechanisms, such as the spin-rotation interaction in which the rotation of the molecular electrons generates a magnetic field at the nucleus. In general, rotational and diffusional motions are important sources of relaxation in fluids. Some mechanisms that make contributions to spin-lattice relaxation will be discussed.

2.5.1 Nuclear Spin Relaxation Mechanisms

There are a number of processes that provide the basis for nuclear spin relaxation. These include the nuclear magnetic

dipole-dipole interactions (DD), the spin-rotation interactions (SR), the quadrupolar interactions (Q), and the chemical shift interactions, (CSA). The overall relaxation rate can be expressed as a sum of contributions from each mechanism.

2.5.2 Dipole-Dipole Interaction

The magnetic nuclei in molecules provide magnetic dipole fields that are proportional to the magnetic moments of the nuclei. These fields fluctuate in magnitude and direction as the molecule tumbles through space. When these random oscillating fields have magnetic field components at the Larmour frequency, the nuclear spin relaxes. This interaction depends upon the correlation time of the tumbling molecule as well as the distance between the interacting nuclei. The dipole interactions can be divided into intramolecular and intermolecular interactions. For both of these types of interactions there is a homo, and hetero-nuclear sub-interaction. These are reflected in the following equations

$$\begin{aligned} \text{For intra-homo: } \frac{1}{T_1^{\text{DD}}} &= \frac{3\gamma_A^4\hbar^2\tau_c}{2r^6} \\ \text{For intra-hetero: } \frac{1}{T_1^{\text{DD}}} &= \frac{\gamma_A^2\gamma_X^2\hbar^2\tau_c}{r^6} \\ \text{For inter-hetero: } \frac{1}{T_1^{\text{DD}}} &= \frac{2N_A\gamma_A^2\gamma_X^2\hbar^2}{Da} \end{aligned} \quad (1)$$

where r is the distance between the interacting nuclei, D is a mutual translational self-diffusion coefficient for the molecules containing A and X , and a is the distance of closest approach between A and X . τ_c is a rotational diffusion correlation time for molecular tumbling. This corresponds to the average time it takes for a molecule to rotate through one radian.

2.5.3 The Spin-Rotation (SR) Interaction

Spin-rotation relaxation of the nuclear magnetization in molecules is due to the intramolecular coupling of the individual nuclear spins to the molecular angular momentum. A fluctuating local magnetic field, which relaxes the nuclear spins, is the result of the collisional reorientation of the molecular rotational angular momentum. For linear molecules such as CO_2 , the spin-rotation contribution to the total spin-lattice relaxation can be expressed as

$$\frac{1}{T_1^{\text{SR}}} = \frac{4C_{\perp}^2 I k T \tau_j}{3\hbar^2} \quad (2)$$

$C_{\perp}$ is the spin-rotation constant and I is the moment of inertia. For a spherical top molecule, the relaxation rate has the form

$$\frac{1}{T_1^{\text{SR}}} = \frac{2C_{\text{eff}}^2 I k T \tau_j}{\hbar^2} \quad (3)$$

C_{eff} is the effective spin-rotation tensor. The τ_j is the correlation time for angular momentum transfer and therefore is closely related to the average time between collisions. The higher the temperature the faster the molecule reorients in accordance with the kT term. The result is that the spin-rotation contribution to the total spin-lattice relaxation

increases with temperature. This is quite the opposite in all other mechanisms examined in this work.

2.5.4 Quadrupolar Relaxation

Quadrupolar occurs when the nuclear electric quadrupole moment, interacts with electric field gradients to provide a very efficient nuclear relaxation process. The equation for these interactions is similar in form to that of the dipole interaction. The electric quadrupolar interaction between spin I and an electric field gradient can be written in the form given in equation (4).

$$\frac{1}{T_1^Q} = \frac{3\pi^2(2I+3)\chi^2\tau_c}{10[I^2(2I-1)]} \quad (4)$$

where χ is known as the nuclear quadrupolar coupling constant and is in units of frequency. The τ_c here is the rotational diffusion correlation time as it appeared in the dipolar equation. Because of its relative efficiency the quadrupolar interaction nearly dominates when quadrupolar nuclei are present.

2.5.5 Chemical Shift Anisotropy

Anisotropic shielding at the nucleus changes with the orientation of the molecule in a static field. Therefore the molecular tumbling modulates the local magnetic field resulting in relaxation. The spin-lattice relaxation rate due to this interaction is proportional to the square of the magnetic field:

$$\frac{1}{T_1^{\text{CSA}}} = \frac{2}{15}\gamma_A^2 B^2 \Delta \sigma^2 \tau_c \quad (5)$$

where Δ is the chemical shielding anisotropy of the nucleus and τ_c has the same meaning as before.

The spin-lattice relaxation can be measured and contributions from each of the mechanisms decoupled to yield dynamic and structural information pertaining to the species of interest. Each of the following sections will contain specific observation techniques and theoretical treatments used to provide insight into the often strange and unpredictable world of supercritical fluids.

Extensive studies have been performed on nuclear magnetic spin lattice relaxation and its dependence on molecular structure and dynamics. This is the subject of several review articles.^{9–12} Decoupling techniques are often used to enhance the signal and to simplify the resulting spectrum. Such decoupling studies also yield the nuclear Overhauser enhancement (NOE), which allows the unique separation of the dipolar interaction from other relaxation interactions. However, decoupling also eliminates multiplet splittings from scalar couplings, thereby preventing direct measurement of some of the spectral features that are required to completely describe the relaxation of coupled nuclear spin systems.

Spin-coherent double-resonance experiments, which avoid this loss of information, and a general numerical method for analyzing the data obtained in relaxation studies of this type may be used.^{13,14} Relaxation processes, described by a system of coupled linear differential equations, determine a variety of time-independent relaxation parameters that contain information on the molecular structure, and dynamic features of the motion. The relaxation parameters in the equations of

motion can then be extracted from the experimental data using standard least squares methods.^{13,14}

For polyatomic gases, nuclear spin relaxation proceeds primarily from the collisional modulation of the molecular rotational angular momentum coupled to the angular momentum of the nuclear spins. Reorientations of molecular angular momentum by collision then give rise to fluctuating internal magnetic fields, that effect the nuclear spins through intramolecular spin-rotation couplings. In addition to the spin-rotation mechanism molecular motional modulation of the chemical shift anisotropy, dipole-dipole and quadrupolar couplings also affect the relaxation rates.

In low-viscosity liquids and gases, spin-lattice relaxation may be treated as a temporal modulation associated with the thermal reorientation of the molecule. The study of spin lattice relaxation contributes to an understanding of molecular dynamics.¹⁵ In dilute gaseous samples of small molecules where the interactions mediating spin relaxation are primarily intermolecular,^{16,17} and the various interaction parameters are known accurately,^{18–21} the study of relaxation reveals features of collisional processes responsible for reorientation of the molecules.^{22–24}

2.6 Line Narrowing

All polyatomic gases possess more than one intramolecular relaxation mechanism. Even the molecule H_2 , for instance, has two competing mechanisms: the spin-rotation and the direct dipole-dipole interaction. In condensed phase molecular hydrogen the contribution of the dipole-dipole mechanism is comparable to that of spin rotation because the distance between the protons is short enough for the dipole-dipole relaxation to be appreciable. In a gaseous system, however, spin rotation is normally the dominant relaxation mechanism. In such experiments high density carbon dioxide can be added to hydrogen isotopomers such as hydrogen deuteride, as suggested by Johnson and Waugh,²³ to shorten the rotational correlation times and thereby lengthen the spin-rotation relaxation time and narrow the resonances in the high-resolution spectra. The H_2 system is difficult to study because of the indistinguishability of the two particles. Thus research on the lower HD symmetry^{18,19,21–23,25–28} provides more information from both the proton and deuteron resonances arising from indirect spin-spin couplings.

Supercritical fluids generally have viscosities 10–100 times lower than that of the normal liquid phase and self diffusion coefficients 10–100 times greater. To the NMR spectroscopist, these properties are of significant benefit in studying quadrupolar nuclei, since the quadrupolar linewidth is proportional to the rotational correlation time. The utility of NMR to study many quadrupolar nuclei has been somewhat limited. Quadrupolar relaxation can be very efficient, leading to broad lines and low sensitivities. In the extreme narrowing limit, the linewidth of these nuclei, $(1/\pi T_2)$ can be written as

$$\frac{1}{\pi T_2} = \frac{3}{8} \left(\frac{e^2 q Q}{h} \right)^2 \left(1 + \frac{\eta^2}{3} \right) \tau \quad (6)$$

where $e^2 q Q/h$ is the quadrupolar coupling constant, τ is the rotational correlation time for the molecular motion, and η is the asymmetry parameter of the electric field gradient

tensor. Various studies have demonstrated the validity of the Stokes–Einstein–Debye equation.²⁹

$$\tau = \frac{A\eta}{T + \tau_0} \quad (7)$$

in which τ is the rotational correlation time, η is the solvent viscosity, T is the temperature and τ_0 is the high temperature intercept. This equation predicts a linear relation between τ and η/T to a limiting value τ_0 attained in the limit as $\eta/T \rightarrow 0$. Comparisons with above equation show that NMR line widths should decrease with decreasing viscosity to a limiting value expected to be related to the free rotor correlation time given by

$$\tau_{\text{FR}} = \left(\frac{2\pi I}{9kT} \right)^{1/2} \quad (8)$$

where I is the moment of inertia about the rotational axis.

2.7 NMR Determination of Structural Dynamics in High-Pressure Fluids

There have been direct spectroscopic probes of the local solvent structure around solutes in supercritical fluids. These include using the solvatochromic scales as in the ultraviolet-visible (UV) absorption of phenol blue in ethylene³⁰ and the fluorescence spectroscopy of pyrene in carbon dioxide.³¹ The use of spectroscopic methods to study the local environment surrounding solute molecules in dilute supercritical fluid mixtures has been reviewed.³² However the use of NMR to determine the local structure within supercritical fluids has thus far been sparse in the literature.

2.7.1 High Pressure NMR Studies of Hydrogen Bonded Liquids

An understanding of molecular interactions between solute and solvent molecules in supercritical fluids (SCF) is essential to an explanation of clustering phenomena, considered responsible for the unique SCF solvating characteristics compared to gases.^{33–35} Although both theoretical^{36–38} and experimental efforts^{39–46} have been made to increase the understanding of these phenomena, a complete picture of clustering in SCFs is still evolving. The accumulation of experimental NMR relaxation data is expected to improve our physical picture of solvent clustering in SCF. Because the nuclear spin–lattice relaxation rates depend on the fluctuating molecular reorientation and molecular collision frequency, their measurement proves to be an effective method for studying such molecular interactions and dynamics in fluids.⁴⁷ One of the advantages of utilizing NMR relaxation data is that they provide not only information, similar to optical methods, on overall molecular motions but also site-specific information on intramolecular motions. The ^{13}C spin–lattice relaxation processes in CO_2 are dominated by spin–rotation interactions.^{48–50} Nuclear spin–lattice relaxation rates have been measured under SCF conditions by Lamb et al.⁵¹ and Etesse et al.^{52–54} for various SCF mixtures. NMR chemical shift measurements⁵⁵ were also used to relate ^{129}Xe chemical shift data to the local solvent structures of SCF Xe. SCF fluid structures in pure methanol,⁵⁶ CO_2 –methane,³⁹ CO_2 –methanol,⁴⁰ and CO_2 –decanol⁴⁰ mixtures have recently been made. The function of the hydroxyl

group in solute-induced solvent clustering in SCF CO_2 appears to be especially important. Earlier developments in high pressure NMR studies of hydrogen bonded liquids may be found in a review article by Lang and Ludemann.⁵⁷

Information on the nature and average rate of molecular motions may be obtained by determining the nuclear spin–lattice relaxation rates of nuclei in the molecules under investigation. The nuclear spin relaxation rate, $1/T_1$, depends on fluctuations in molecular reorientations as a consequence of molecular collisions, where T_1 is the time constant defining the exponential return of a perturbed nuclear spin to its equilibrium state. Many nuclear spin interaction mechanisms affect T_1 values. Among them, spin–rotation, quadrupolar and dipolar interactions are the most important ones at sub- and supercritical densities. Detailed descriptions of spin–rotation, quadrupolar and dipolar interactions may be found in the review articles by Grant et al.⁵⁸ and Jameson.⁵⁹ Briefly, determination of NMR nuclear relaxation rates provides the angular momentum⁵⁹ and rotational reorientation correlation times⁵⁸ from the spin–rotation and quadrupolar/dipolar interactions, respectively. Spin–rotation interactions are directly related to molecular collision frequencies and depend on macroscopic properties such as fluid density and temperature. Dipolar and quadrupolar interactions, however, are often related to fluid viscosity and temperature. Since the fluid viscosity may be treated as a function of local density in the compressible regions of CO_2 , both correlation times may be considered as functions of local densities. Therefore, clustering phenomena in SCF resulting in fluctuations of local density may in principle be observed by NMR relaxation measurements.

The magnitude of the NOE effect is given by⁶⁰

$$\text{NOE}(A\{X\}) = \frac{I_A^*}{I_A^0} \quad (9)$$

where I_A^* is the integrated intensity of a decoupled spectrum with saturation of the nucleus X , and I_A^0 is the equilibrium intensity of A in the coupled spectrum. The maximum possible NOE of $^{13}\text{C}\{^1\text{H}\}$ occurs when ^{13}C and ^1H relax only by the dipolar mechanism given by⁶⁰ and is given by

$$\text{NOE}(\text{max}) = 1 + \left(\frac{\gamma_{\text{H}}}{2\gamma_{\text{C}}} \right) = 2.988 \quad (10)$$

where γ_{H} and γ_{C} are the magnetogyric ratios for ^1H and ^{13}C , respectively. The NOE effect may be determined as a ratio of spectral intensities with proton decoupling to that of gated proton decoupling. Since the ^{13}C in CO_2 does not exhibit an NOE, its signal intensity may be used as a fiducial reference.

2.8 Significant Mechanism in Spin–Lattice Relaxation: Overall Rotational Motion

In general, the overall rotational motions of solute molecules depend on the intermolecular frictional forces between the solute and solvent molecules and, therefore, are dependent upon the solvent viscosity. The solvent viscoelastic response, in turn, is also dependent on various relaxation mechanisms of solvent molecules. Internal rotational motions including various local isomerization movements are driven by torsional forces.⁶¹

The rotational reorientation correlation time, τ_c , may be extracted from NMR spin–lattice relaxation time measurements, within the *extreme narrowing* limit, using the following expression⁶⁰

$$T_{1,DD}^{-1}({}^{13}\text{C}) = \frac{\nu\gamma_C^2\gamma_H^2\hbar^2\tau_c}{r^6} \quad (11)$$

where r is the bond distance between ${}^1\text{H}$ and ${}^{13}\text{C}$ (measured as 1.085 Å), and ν is the number of protons directly attached to the ${}^{13}\text{C}$ nucleus. The dipole–dipole relaxation rate, may be obtained from the standard relationship between the overall T_1 and NOE measurements:⁶⁰

$$\text{NOE} = 1 + \frac{\gamma_H}{2\gamma_C} \frac{T_{1,DD}^{-1}({}^{13}\text{C})}{T_{1,\text{Tot}}^{-1}({}^{13}\text{C})} \quad (12)$$

The reorientation correlation time obtained in this manner is an average assuming isotropic reorientation. This correlation time may be related to a rotational diffusion coefficient by assuming that each nuclear environment is roughly spherical and rotates randomly.⁶²

$$\tau_c = \frac{1}{6D} \quad (13)$$

From the temperature dependence of rotational diffusion coefficients at fixed viscosity, one can determine effective rotational activation energies.

2.9 CO₂ Clustering

The rotational reorientation correlation time, τ_c , can be expressed by a modified Stokes–Einstein–Debye (SED) equation⁶³

$$\tau_c = \frac{\eta V_p}{kT} f_{\text{stick}} C + \tau_0 \quad (14)$$

where η is the fluid viscosity, V_p is the volume of solute molecule, f_{stick} is a well-defined shape parameter dependent only on the structure of solute molecules,⁶⁴ C is a boundary parameter dependent on the nature of the solute and solvent and upon their concentration, and finally τ_0 is the free-rotor correlation time. The success of this model strongly depends on the selection of parameters C and f_{stick} . Recently, Roy et al.⁶⁴ noted that the Dote, Kivelson, and Schwartz (DKS) model⁶³ is the best model for predicting reorientational correlation times for solutes with radii up to about 4.5 Å. Anderson and Kauffman⁶⁵ further modified the calculation of the smallest volume of free space per solvent molecule, ΔV , in the DKS model, and more recently, these two workers⁶⁶ related fluid viscosity and the parameter C in the SED model to the local density by introducing a radial distribution function into the hydrodynamic model. These modifications^{65,66} by Anderson and Kauffman are referred to as the AK model.

In the AK model, the viscosity for a fluid is expressed as a function of local density ρ_{12}^1 by equation 4.7 described by Jossi et al.⁶⁷

$$[(\eta - \eta_0)\xi_T^y + 1]^{1/4} = 1.023 + 0.23364\rho_r + 0.58533\rho_r^2 - 0.40758\rho_r^3 + 0.09324\rho_r^4 \quad (15)$$

where $\rho_r = \rho_{12}^1/\rho_c$ and $\xi_T = (T_c/M^3 P_c^4)^{1/6}$. ρ_c , T_c , and P_c represent the critical density, temperature, and pressure, respectively. M is the molecular weight in the unit of g mol⁻¹. The local density of is related to the bulk density ρ by a radial distribution formalism

$$\rho_{12}^1 = \rho\{1 + F[g_{12}(r)]\} \quad (16)$$

where $F[g_{12}(r)]$ is an integral equation in the pair distribution function, $g_{12}(r)$, over the spatial coordinates and r is the distance between solvent and solute molecules. $F[g_{12}(r)]$ is a measure of the excess solvent density near the solute molecule and is treated as an adjustable parameter in the AK model. When $F[g_{12}(r)] = 0$, the local density equals the bulk density, and when $F[g_{12}(r)] = 1.0$, the local density is twice the bulk density.

In the AK model, the parameter $C(\rho_{12}^1)$ equivalent to C in the SED model, is also treated as a function of local density. According to the DKS model

$$C(\rho_{12}^1) = \frac{f_{\text{slip}} V_p}{f_{\text{slip}} V_p + \gamma V_p} \quad (17)$$

where f_{slip} is a factor for the slip boundary condition whose value estimated from f_{stick} by the method reported by Hu and Zwanzig⁶⁸ and γ is defined as

$$\gamma = \left(\frac{\Delta V}{V_p}\right) \left[4 \left(\frac{V_p}{V_s}\right)^{\frac{2}{3}} + 1\right] \quad (18)$$

In equation (18), V_s is the solute molecular volume and ΔV is the free space volume for a solvent molecule. For supercritical fluids in their compressible regions, a large variation in the free space is expected, and ΔV is given by equation (19) relating molecular weight (MW) and local density:

$$\Delta V = \frac{\text{MW}}{\rho_{12}^1} - V_s \quad (19)$$

Therefore, the parameter $C(\rho_{12}^1)$ is expressed as a function of local density ρ_{12}^1 though the free space volume ΔV .

Combining equations (18) and (19), the AK version of the SED equation may be expressed as⁶⁶

$$\tau_c \equiv \frac{\eta(\rho_{12}^1) V_p}{kT} f_{\text{stick}} C(\rho_{12}^1) + \tau_0 \quad (20)$$

Equation (20) relates the reorientation correlation time, τ_c , to the solvent local density at a given temperature. By performing a comparison experiment on *trans,trans*-1,4-diphenylbutadiene (DPB) solute in CO₂, Anderson and Kauffman⁶⁶ also observed that CO₂ solvent clustering only occurs in the vicinity of *trans*-4-(hydroxymethyl)stilbene (HMS) molecules. Because the extended π -electron systems existing in DPB and HMS are similar, Anderson and Kauffman concluded that the OH group in HMS is responsible for the association between the solute and solvent molecules. The one-to-one association between solute and solvent molecules may initiate further CO₂ clustering whenever strong many-body interactions affect the solvent structure in supercritical

fluids in the compressible density region. The CO₂ clustering gradients observed along the aliphatic chain of 1-decanol molecules in the Bai et al.³⁹ study appear to support the observations by Anderson and Kauffman.

To verify further the importance of alcohol enhanced clustering, the same procedure was applied to a CO₂–methanol mixture,⁶⁹ where a specific association between CO₂ and CH₃OH has been observed also by the IR studies.⁴² Such solvent-solute interactions may initiate CO₂ solvent clustering.⁶⁶ The low-pressure limit free-rotor correlation time can be calculated using the following expression⁷⁰

$$\tau_0 = \frac{2\pi}{9} \left(\frac{I_{\perp}}{kT} \right)^{1/2} \quad (21)$$

where $I_{\perp}$ is the perpendicular component of the moment of inertia for methanol molecules. The calculated τ_0 from equation (21) is 0.20 ps, which agrees well with the 0.17 ps from fitting the low-density data.

2.10 More Evidence for the Formation of CO₂ Clusters in the Vicinity of Methanol

As stated above, NOE measurements allow the separation of the dipole–dipole contributions to spin–lattice relaxation rates from other mechanistic contributions. For methanol, the remaining relaxation contributions result essentially from the spin–rotation mechanisms described previously.⁶⁹ These spin–rotation relaxation rates allow one to calculate an angular momentum exchange correlation time, τ_J , which is strongly dependent on the fluid density. Methanol is a quasi-symmetric top molecule, but the relation between ρ , and spin–rotation relaxation rates for symmetric top molecules may be used as a good approximation for T_1^{SR} . The expression⁷¹ is

$$\frac{1}{T_1^{\text{SR}}} = \frac{2\pi^2}{\alpha} C_{\text{eff}}^2 \tau_J \quad (22)$$

where pull down $\alpha = \hbar^2/(2kT I_{\perp})$ and $I_{\perp}$ is the perpendicular part of the moment of inertia for methanol. The effective spin–rotation, C_{eff} , may be expressed as

$$C_{\text{eff}}^2 = k_1 C_a^2 + k_2 C_a C_d + k_3 C_d^2 \quad (23)$$

In equation (23), the structure parameters, k_i , only depend on molecular structure. C_a and C_d are the isotropic and anisotropic components of the spin–rotation tensor. Therefore, in principle, an experimental angular momentum correlation time, τ_J , may be estimated using equation (22). Since τ_J is linearly related to the time between molecular collisions, τ_{BC} , one may calculate τ_J using a gas kinetic theory. The slope of this linear relationship, called an effective collision number and referred to as Z ,⁷² provides the average number of collisions needed for an effective molecular angular momentum exchange. This number is found to be between 1.4 and 3.4 for many collision pairs (cf. Table 3 in Ref.⁷²). In the use of a hard-sphere model (HSM) for calculating cross sections, choosing the effective collision number of two appeared to be a good approximation in the work of Maryott, Malmberg,

and Gillen,⁷² and therefore, this value is used in the following discussion. The expression for computing τ_J is given by⁷³

$$\tau_J = \frac{Z}{\rho \bar{v} \sigma_K} \quad (24)$$

where ρ is fluid density, $\bar{v}$ is the average velocity of molecules, and σ_K is the kinetic collisional cross section between solute and solvent molecules. Both $\bar{v}$ and σ_K may be estimated from molecular properties of the solute and solvent. If the density term, ρ , in equation (24) is replaced by a local density [cf. equation (16)], the estimated τ_J becomes a function of the excess solvent density parameter, $F[g_{12}(r)]$. In this case, equation (24) becomes

$$\tau_J = \frac{Z}{\rho \{1 + F[g_{12}(r)]\} \bar{v} \sigma_K} \quad (25)$$

There is good agreement between theoretical and experimental data when an increase in local density is employed in the predictions of τ_J . This provides additional evidence for the formation of SCF solvent clustering in the vicinity of hydrogen bonding solute molecules. Supposedly, these interactions are induced by the hydroxyl functional group present in alcohol molecules.

2.11 NMR Determination of Self-diffusion Coefficients in High-pressure Fluids

Many methods exist for measuring the diffusion coefficients of fluids. However, the experimental accuracy of many of these is quite limited.^{74,75} Furthermore, methods that give reliable results in the low pressure regime are not always suitable at high pressures because the inverse dependence of the diffusion coefficient on pressure makes for experiments that take an inordinately long time. The most widely reported method for the measurement of diffusion coefficients in the SCF state is a gas chromatographic method based on Taylor dispersion, which has proven unreliable at lower pressures.^{76–78}

The only other methods that can be utilized for this measurement in SCFs are photon correlation spectroscopy^{79,80} and NMR.^{81,82} They are not widely used at this time because the equipment is very expensive and their application to industrially important SCF's is still in its infancy. The use of the NMR technique has been confined to the measurement of self diffusion coefficients.^{81,82}

3 INSTRUMENT REQUIREMENTS FOR HIGH-PRESSURE NMR

In order to perform NMR experiments under high pressure, it is necessary to devise a convenient means to control the pressure, temperature and sample concentration while it is inside the magnet. Two basic approaches to the design of high pressure NMR experiments have been reported: (1) construction of a probe which is capable of achieving the necessary pressures, referred to as the *high pressure probe technique*,⁸³ or (2) fabrication of a high pressure cell which can be used in a standard commercial NMR probe, referred to as the *high pressure cell technique*.

The very first high pressure NMR experiment was performed in 1954 by Benedek and Purcell.⁸⁴ They used a

hydrostatic high pressure probe capable of holding pressures up to 10 000 atm. For deformable samples the high pressure probe technique requires a sealed sample cell which incorporates a volume change mechanism such as bellows or a mercury column.⁸⁵ The cell is surrounded by a RF coil and is located inside a pressure vessel small enough to fit inside the NMR magnet. The high pressure probe technique usually offers higher sensitivity because of a better filling factor for the receiver coil. It also allows for higher pressures and is usually safer to work with. The disadvantages are that they require a more elaborate and expensive design and are therefore not suitable for a routine NMR laboratory. The approach to a high pressure probe has continually been developed by Jonas et al.⁸⁶ with improvements to pressure vessel design and electrical feed-throughs. The most recent advances to the probe design for studying supercritical fluids include the toroidal coil⁸⁷ and cavity⁸⁸ design by Rathke et al.

The high pressure cell technique allows the experiments to be performed in a commercial NMR probehead, thereby eliminating the need to alter the basic probe design. The earlier versions of high pressure cells experienced lower sensitivity and reduced working pressures. Yonker et al. designed a simple and safe method by coiling a fused silica capillary tube inside a commercial 5-mm NMR tube.⁸⁹ Newer cell designs have improved these limitations providing a more convenient and cost-effective means of carrying out high pressure NMR experiments. Roe et al.⁹⁰ designed the first cell made of single crystal sapphire and Horvath et al. later improved this design.^{91,92} Pressure control while the cell is in the magnet is a major issue in the cell design. The previously reported designs of the sapphire NMR cells were unable to independently control both the sample temperature and pressure. In the Bai et al. design⁹³ a movable piston is used to control the sample pressure (see Figure 2). With this design it is possible to control temperature and pressure independently over a wide range of conditions while keeping the relative molar concentration ratios of the sample mixture intact. The sample volume must be restricted to the active coil in order to eliminate errors introduced through molecular diffusion between polarized and nonpolarized volume elements within the cell. Recently a high pressure cell constructed of high-performance polymers, such as poly(etherether ketone) (PEEK), was developed by Wallen et al.⁹⁴ with the purpose of simplifying the cell design to allow for more routine experiments on supercritical fluids.

The very first high pressure probe was made of a beryllium copper alloy (Berylco 25). This alloy was used due its strength and nonmagnetic properties, but does require special heat treatment and can have significant variations in the level of paramagnetic impurities. Berylco 25 is stable up to 10 000 atm and permits a temperature range of -10°C – 80°C . Titanium alloys (IMI-680) are now more commonly used as they require no special heat treatment during machining and retain their strength up to 400°C and 5000 atm. For even higher pressures, up to 100 kbar, the diamond anvil method can be used.⁹⁵ This method can only be used with very small samples so most studies concern sensitive nuclei, although a study on ^{13}C has been reported.

4 SUPERCRITICAL FLUID APPLICATIONS

Most of the high pressure NMR studies of supercritical fluids have involved measuring chemical shifts, such as ^1H ,⁹⁶

Figure 2 Schematic diagram of the high pressure piston NMR cell capable of independently controlling temperature, pressure and sample concentration

of both polar and nonpolar solute molecules in the dense phase fluid. Increased reaction rates of certain reactions in supercritical fluids has been attributed to specific solvent-solute and solute-solute interactions. By studying these specific interactions by NMR further insight into the variation of the surroundings of the solute molecules with the density of the supercritical fluid is obtained and can be compared to other experimental techniques, such as UV and vibrational spectroscopy.

Using a fused silica capillary cell an in situ photolysis study of organometallics in supercritical fluids was performed where the ligand exchange with the metal center was directly observed.⁹⁷ High pressure NMR was also used to determine the fundamental dynamic and electronic properties of the organometallic complexes in the SCF through the investigation of the spin-lattice relaxation times, T_1 , and NMR magnetic shielding constants, σ .

Another interesting application of supercritical fluids is to use them as solvents for comprehensive NMR studies of large proteins. In conventional solvents large proteins (over 30 kDa) tumble too slowly and correspondingly the spin-spin relaxation times (T_2) become shorter, making some standard experiments unreliable. By encapsulating the protein in a reverse micelle dispersed in a low viscosity fluid, such as a supercritical fluid, the tumbling correlation time (τ_m) of the protein is reduced thereby increasing T_2 .⁹⁸ This results in narrower lines in the spectrum.

High pressure NMR has also been used to investigate phase behavior of binary solvent systems in order to obtain vapor-liquid equilibrium (VLE) values. Usually VLE values of supercritical fluid solutions are obtained using variable volume view cells and off-line analysis techniques. By using NMR, this process can be simplified and made more efficient for numerous solvent systems. This technique is especially suitable for hydrocarbon containing solvent molecules as detection of solvent protons in both the liquid and vapor phase can be detected simultaneously.⁹⁹

An advantage of using supercritical fluids as reaction media for chemical reactions is that gaseous reagents are completely miscible with the solvent. In catalytic reactions such as hydrogenations and hydroformylations where H_2 and CO are reactants this can have a significant impact on both the yield and selectivity of the desired products. Since only one phase is present in the supercritical system, stirring to achieve gas-liquid mixing is unnecessary. By studying these reactions in situ by NMR valuable information regarding the mechanism can be obtained.¹⁰⁰ In situ NMR was used to optimize the iridium catalyzed enantioselective hydrogenation of imines in supercritical CO_2 . By studying the specific interactions between substrates and products with CO_2 conclusions about the different reactivities of structurally similar substrates were obtained.¹⁰¹

1 INTRODUCTION

Perhaps the most direct observables in NMR spectra are the positions of the resonances, which are generally reported as chemical shifts relative to a standard position. The very existence of useful spectra depends upon chemical shift dispersion, so that nuclei in chemically distinct positions resonate at different frequencies. For peptides and proteins it is convenient to divide the origins of chemical shift differences into two components: the first arises from variations in the local electronic environment, so that aromatic and aliphatic protons, for example, have characteristic shifts that differ from each other and from amide protons. A second component of chemical shift dispersion occurs with nominally identical protons, such as valine H α , due to variations in the nature of adjoining residues and especially to conformational differences in secondary and tertiary structure. While there is no sharp distinction between these two components, the ‘local’ effects usually arise from variations in shielding by electrons in the bonds that contain (or are adjacent to) the resonating nucleus, whereas the longer range effects are generally ‘through-space’ interactions involving functional groups separated by many chemical bonds from the nucleus in question.

This article surveys both empirical trends and theoretical approaches to understanding chemical shift trends in amino acids, peptides and proteins. The main emphasis is on connections between conformation (especially secondary and tertiary structure) and chemical shift. It has been clear for some time that chemical shifts in proteins and peptides depend upon structure in a reasonably regular way, so that, for example, the shifts in structurally homologous proteins are themselves homologous.^{1,2} One force driving recent reexaminations of the origins of chemical shift dispersion has been the rapid growth in the number of protein and peptide assignments. Many of these are now available in a relational database that contains about 140 000 assignments.³ While much of the ‘information content’ of these data remains to be discovered, the following two sections outline some of the clear trends that emerge from surveys of shift distributions

2 EMPIRICAL SURVEYS OF CHEMICAL SHIFTS IN PEPTIDES AND PROTEINS

2.1 Peptides

Short, unstructured peptides provide a useful reference point for many examinations of protein shifts, since they embody most of the local contributions that depend upon the chemical nature of the amino acid side chain, but lack the longer range contributions characteristic of folded proteins. The values most often cited are those of Bundi and Wüthrich (for protons),⁴ and Richarz and Wüthrich (for ¹³C),⁵ based on the peptide H-Gly-Gly-X-Ala-OH, where X represents any of the 20 common amino acids. Table 1 lists these values for the backbone nuclei. It is common practice to define a ‘structural’ shift as the difference between an observed resonance position in a protein or structured peptide and these ‘random coil’ values.

In principle, peptide shifts like these could be computed from first principles using quantum chemistry calculations. At present such calculations are limited to relatively small molecules in the gas phase, and are generally not of routine ‘chemical’ accuracy, at least when one is considering nuclei in different bonding environments.⁶ The situation is changing rapidly, however, and ab initio calculations with reasonable basis sets are now feasible for protein fragments such as amino acids and dipeptides.^{7–11} Such calculations appear to be able to rationalize the dependence of some shifts on backbone dihedral angles, and point the way to the exploration of other effects such as hydrogen bonding and external electric fields. Because a variety of effects are important in influencing shifts, reliable computational studies on amino acids and peptides could have an important impact in the next few years.

2.2 Proteins

The primary empirical study of chemical shifts in proteins is that of Wishart et al.¹² who correlated observed chemical shifts and secondary-structure assignments in over 70 proteins, and computed averages and distributions for shifts in helix, β -strand, and coil configurations. Table 1 gives the results (not sorted by secondary structure) for a larger sample drawn from the BioMagResBank database.³ There are only minor differences between the proton averages given in Table 1 and the earlier results; for the amide ¹⁵N shifts, results for M, P and T differ by more than 1 ppm between the two compilations; for ¹³C α , C, M, N, Q and W differ by at least 1 ppm; the majority of values for the carbonyl ¹³C shift differ by at least this much, perhaps reflecting the small number of available shifts even now. As might be expected, the C α and H α nuclei, which are closest to the side chain, show a strong correlation between the median shift observed in proteins and the ‘random coil’ peptide value: linear correlation coefficients are 0.95 and 0.99 for H α and C α respectively. On the other hand, median shifts in proteins for the amide proton and carbonyl carbon are only weakly related to the peptide random coil shifts, with correlation coefficients of 0.11, and 0.56, respectively. This suggests that longer range interactions, such as hydrogen bonding, may be important in influencing these shifts.

^aData extracted from version 1.0 of the BioMagResBank database.³ For each shift, the first three columns list the number of shifts, the median value and the standard deviation SD about the mean. Column labeled 'rc' gives peptide shifts for H-Gly-Gly-X-Ala-OH from Bundi and Wüthrich⁴ and Richarz and Wüthrich.⁵

3 CHEMICAL SHIFTS AND SECONDARY STRUCTURE

Considerable attention has been paid to ways in which the H α shift reflects local secondary structure. It has been recognized for some time that β -sheet regions show high-frequency shifts for this resonance, while helical regions show low-frequency shifts. In the Wishart et al.¹² survey, the mean H α positions in helices and sheets differ by nearly 0.8 ppm, and there is remarkably little overlap between the two distributions.

The same general trend is found for amide protons, whereas H β shifts move in the opposite direction by a smaller amount. Amide protons at the N-terminus of helices tend to be shifted to high frequency compared with those at the C-terminus. These relationships are in many cases clear enough to drive secondary-structure assignments in proteins,^{13,14} and to gain a qualitative idea of structural differences among homologous systems. It has been shown that this dependence of H α and H β shifts on secondary structure can be explained in terms of peptide group contributions, as outlined below.¹⁵

These ideas may also be of use for linear peptides, where conformational heterogeneity hampers quantitative NOE-based structure calculations. For example, amide proton shifts in model helical peptides are often periodic (with a 3–4 residue repeat pattern);^{16,17} amphipathic helices show a periodic behavior that appears to be related to curving of the helix axis;^{18,19} and it may be possible to characterize helices of marginal stability through an analysis of the solvent dependence of backbone shifts.²⁰

The relationship of ¹⁵N and ¹³C shifts to secondary structure is also of considerable current interest.^{9–12,21} C α and carbonyl shifts exhibit a strong correlation with secondary structure, both moving to higher frequency in helical conformations and to lower frequency in β -strand or extended configurations. As with H α shifts, there is surprisingly little overlap between the distributions, which suggests that reliable conformational conclusions may be drawn, and the C α shift has been used as a site-specific probe of the helix/coil transition in linear peptides.²² There are also indications from solid state studies of peptides that the carbonyl ¹³C resonance moves to higher frequency with decreasing CO $\cdots$ HN hydrogen-bond length,^{23–27} a result that is in rough accord with quantum chemical calculations.²⁶ C β shifts also show systematic differences between helices and sheets, but with much more overlap in the observed distributions.

The situation for amide ¹⁵N shifts in proteins (as with amide protons) is less clear. There are general differences between shifts in helix and sheet structures of about 3 ppm, but the overlap between the two distributions is often greater than this, so that it is difficult to draw simple conclusions from a given set of shifts.^{12,28,29} There is a correlation between amide proton and amide ¹⁵N shifts, suggesting that similar physical effects are influencing both. There is some evidence that ¹⁵N shifts may be periodic in helices, reflecting the local structure, but the relationship does not appear to be a simple one.^{16,30}

4 CHEMICAL SHIFTS AND TERTIARY STRUCTURE

In both organic chemistry and biochemistry, empirical analyses of the effects of ‘distant’ substituents on chemical shifts have played an important role for many years.³¹ There are generally two such types of interaction: magnetic fields arising from anisotropies in the magnetic susceptibilities of distant functional groups, and electric fields created by distant dipoles or charges. The former are strongest with conjugated or partially delocalized electrons (such as in aromatic rings or peptide groups) where there are significant anisotropies in group magnetic susceptibilities.^{32–34} These groups then respond to an external spectrometer field B_0 to create a local magnetic field which can augment or oppose B_0 .³⁵ The electrostatic fields of distant groups influence chemical shifts indirectly, by polarizing chemical bonds, and thus contributing to shielding or deshielding of the nuclei.³⁶ These mechanisms are considered in more detail in the following paragraphs.

4.1 Ring Current Calculations

The general form of empirical theories is $\sigma_{rc} = iBG(\mathbf{r})$ where $\mathbf{r}$ is the vector from the observed proton to the aromatic ring, $G(\mathbf{r})$ is a geometric factor, and i and B are constants.^{31,34} It

is conventional to incorporate in B those constants that would yield the expected contribution from a benzene ring, and to use $i\#$ (the ‘ring current intensity’ factor) to represent the ratio of the intensity expected for the ring in question to that of a benzene ring. There have been several attempts to estimate these factors, based on both quantum mechanical and empirical calculations.^{37,38}

Two commonly used parameterizations of the geometric factors were proposed by Johnson and Bovey³⁹ and by Haigh and Mallion.³⁴ In the latter model, which is one of the simplest to implement, the geometric factor is

$$G(\mathbf{r}) = \sum_{ij} s_{ij} \left\{ \frac{1}{r_i^3} + \frac{1}{r_j^3} \right\} \quad (1)$$

Here r_i and r_j are the distances from ring atoms i and j to the proton, and s_{ij} is the area of the triangle formed by atoms i and j and the proton projected onto the plane of the aromatic ring. The sum is over the bonds in the ring. The Johnson–Bovey model sets up ‘rings’ of current above and below the plane of the atoms, and computes fields from this model. There appears to be very little difference between the two models, except at very short distances.

The heme group is an important special case for ring current calculations, and a variety of empirical calculations have been carried out.^{40–43} A simple model that gives good results treats the heme as five rings: four for the pyrroles, and one ‘macrocycle’ that traverses the large conjugated ring in the canonical valence-bond structure. Cross and Wright⁴³ compared the results of this and other models with a dataset composed of protein and model compound shifts, and Ösapay and Case³⁸ used a larger heme protein database, including cytochromes c , b_5 , and c_{551} and myoglobin. The empirical formulas appear to reproduce the observed behavior quite well.

4.2 Peptide Group Contributions

It has been recognized for some time that the magnetic anisotropy of the peptide group is likely to contribute significantly to chemical shifts in proteins. McConnell³⁵ has shown that when the observed proton and the ‘source’ of the magnetic anisotropy are far apart, the contribution to the local shielding tensor depends upon the magnetic anisotropy of the distant group:

$$\sigma_m = (3L_0R^3)^{-1} \sum_{i=x,y,z} \chi_{ii}(1 - 3\cos^2\theta_i) \quad (2)$$

Here L_0 is the Avogadro constant, R is the distance from the proton to the distant group, χ_{ii} is a component of the magnetic susceptibility tensor, and θ_i is the angle between the i axis and the radius vector $\mathbf{R}$. Since there is no direct method for measuring the magnetic anisotropy of a peptide group within a protein, all estimates of these effects are to some extent empirical. Data for formamide⁴⁴ suggest that the peptide group is nearly axially symmetric about the out-of-plane axis, with an anisotropy $\Delta\chi$ of $-5.1 \pm 0.6 \times 10^{-6}$ erg (G²-mol)⁻¹. This value is in good agreement with the one obtained using an empirical theoretical approach developed by Pauling.³³ -5.4×10^{-6} erg (G²-mol)⁻¹.

Alternative models for peptide groups can be constructed by adding contributions from individual atoms⁴⁵ or bonds,^{46–48} rather than using parameters for the peptide group as a whole. These alternative methods give generally similar results.^{49,50}

Contributions from peptide groups calculated in this way can explain to a large extent the observed behavior of $H\alpha$ chemical shifts as a function of local secondary structure.¹⁵ Because of the R^{-3} distance dependence in equation (2), the neighboring peptide groups have the greatest influence, so that the shift depends to a large extent on the backbone dihedral angles ϕ and ψ , which determine the geometric relationship between the peptide planes and the $H\alpha$ position.

4.3 Electrostatic Contributions

A significant contribution to chemical shifts can also arise from distant charges and dipoles, which can polarize the C–H bond and thereby increase or decrease the local shielding by electrons. The most significant term is expected to be proportional to the projection of the local electric field onto the C–H vector:

$$\sigma_{\text{el}} = AE(\text{C-H}) \quad (3)$$

Buckingham³⁶ suggested that an appropriate value for A would be $-2 \times 10^{-12} \text{ esu}^{-1}$, but this magnitude clearly depends upon the way in which local electric fields are estimated. Most estimates to date have been based on Coulomb's law using partial charge models from molecular mechanics force fields, but this approach ignores important solvent effects that screen charge interactions, and further work in this area is needed.

The relative importance of various contributions is expected to be different for protons than for heavier nuclei. Ring current and magnetic anisotropy contributions will contribute the same absolute shift for all nuclei, and hence should be less important for nuclei like ^{13}C or ^{15}N that have large chemical shift ranges (compared with protons). These heavier nuclei, on the other hand, are more sensitive to electrostatic effects than are protons, probably because of the ability of electric fields to polarize their occupied p shells, which are unoccupied for hydrogen,⁵¹ and some interesting attempts have been made to correlate shifts in proteins with estimates of the local electric fields.^{52,53}

The analysis of chemical shift patterns using these ideas has a long history in organic chemistry.^{31,34,46} Recently, several groups have shown that such calculations can explain a large portion of the chemical shift dispersion seen in globular proteins.^{38,47,48,54,55} For example, Ösapay and Case³⁸ analyzed proton shifts from 17 proteins whose X-ray crystal structures had been determined; for 5678 protons bonded to carbon they obtained a linear correlation coefficient of 0.88 between the calculated and observed structural shifts, with an rms error of 0.23 ppm; for side-chain protons in nonheme proteins the rms error was 0.18 ppm, and for methyl groups it was 0.13 ppm. Computer codes that implement these ideas are available from the author, and equivalent code is part of the AMBER molecular modeling package, which also allows refinement of structures using penalty functions based on chemical shift formulas.⁵⁶ Initial applications to myoglobin⁵⁷ suggest that this idea may be a feasible and useful approach.

5 CONCLUSIONS

There is little doubt that the use of chemical shift information for peptides and proteins will continue to grow as a source of structural information. The $H\alpha$ and $C\alpha$ shifts appear to provide a reliable indicator of local secondary structure, and useful theories are available for magnetic interactions with aromatic rings and peptide groups. Electrostatic interactions (including hydrogen bonding and solvation effects) are less well understood. Ab initio electronic structure calculations are beginning to address problems of interest to peptide and protein chemists, and this, together with empirical analyses of larger numbers of shifts, should provide new insight into the origins of chemical shift dispersion.

1 INTRODUCTION

Situated at the barrier between the interior and exterior of a cell or organelle, membrane proteins execute a variety of vital functions, including energy transduction (i.e. conversion of energy between different forms) and signal transduction (i.e. triggering a cascade of events in response to an environmental effector). The rhodopsins are light-transducing membrane proteins with a chromophore formed by a retinal molecule linked to the protein (known as the opsin) via a Schiff base with a lysine residue (Figure 1). Most rhodopsins are signal transducers: absorption of a photon induces a change in the rhodopsin that activates a primed system, leading to a visual response (e.g. in mammals) or phototactic response (e.g. in algae and archaeobacteria). However, two energy-transducing rhodopsins have been found in halophilic archaeobacteria: in these cases, absorption of a photon results in transport of an ion across the membrane, against its gradient, resulting in conversion of radiant energy into electrochemical energy which can be stored. One of these energy-transducing rhodopsins, known as bacteriorhodopsin because it was the first rhodopsin discovered in a unicellular organism, pumps protons and the other, known as halorhodopsin, pumps halide ions.

Bacteriorhodopsin (248 amino acids, 26 kDa) is the most thoroughly studied membrane protein. This is because it is a major product of *Halobacterium salinarium* (previously also known as *Halobacterium halobium*), and crystallizes in the plane of the membrane to form patches with 2D hexagonal order, from which all other proteins are excluded.¹ These

Figure 1 Protonated Schiff base of all-*trans*-retinal with a Lys side chain. X^- is the Schiff base counterion. The carbons atoms are identified according to convention by numbers on the retinal and Greek letters on the Lys residue

patches (known as ‘purple membranes’ due to the color of the pigment) are readily separated from the rest of the cell membrane and are stable and functional over an exceptionally wide range of conditions (including pH values, ionic strengths, and temperatures). Thus, it is relatively easy to prepare large samples of the protein in its native form. Due to the 2D crystalline order in the membranes, it has been possible to construct 3D electron density maps from electron micrographs taken over a range of tilt angles.² These studies show that the protein folds into a bundle of seven transmembrane helices that encapsulates the retinal chromophore. Chemical studies have shown that the retinal Schiff base is formed with Lys216.³ Neutron diffraction studies find that the retinal is located near the center of the membrane with the ionone ring closer to the extracellular side than the Schiff base.

Figure 2 shows the relationships between the functionally important forms of bacteriorhodopsin. In the dark, there is a thermal equilibrium between bR_{555} and bR_{568} , where the subscript indicates the wavelength of maximum visible absorbance. The photoproducts of bR_{555} (not shown) decay to bR_{568} , so that bR_{555} disappears upon light adaptation. The photocycle of bR_{568} is responsible for proton transport. The initial photoreaction is the isomerization of the chromophore from all-*trans* in bR_{568} to 13-*cis* in J_{625} . The proton on the Schiff base is lost in the L_{550} – M_{412} transition, and restored in the M_{412} – N_{520} transition. FTIR and kinetic studies, of wild-type and mutant samples, indicate that the immediate proton acceptor is Asp85, and the immediate proton donor is Asp96. However, the proton pathway traverses the entire membrane, and pumping occurs because a proton is released into the extracellular medium in the first half of the photocycle and taken up from the cytoplasm in the second half of the photocycle. The central question regarding the mechanism of bacteriorhodopsin is how this switch occurs: what prevents the system from being reprotonated from the extracellular side? For *Halobacterium*, bacteriorhodopsin

Figure 2 Relationships among the functionally important forms of bacteriorhodopsin. Subscripts indicate the wavelength of maximum visible absorbance. The chromophore is photoisomerized from all-*trans* to 13-*cis* in the bR_{568} to L_{550} photoreaction. The Schiff base is protonated in all but the M-states

provides a solar-powered alternative to respiration for creating the proton electrochemical potential gradient that is required for regeneration of ATP from ADP (the 'proton motive' force of the chemiosmotic mechanism).

Bovine rhodopsin (348 amino acids, 40 kDa) is the most thoroughly studied visual pigment, due to Western dietary habits. Rhodopsin is solubilized and purified from the rod cells of the retina, and then reconstituted into lipid bilayers. Although it does not naturally form a crystalline lattice, it can be induced to do so, and electron cryomicroscopy of such preparations indicates that rhodopsin also forms a bundle of seven transmembrane helices.⁴ The retinal Schiff base is formed with Lys296,⁵ and the Schiff base counterion is Glu113.^{6,7} Figure 3 shows the photointermediates of rhodopsin. In the initial photoreaction, the 11-*cis*-retinal in rhodopsin is isomerized to the all-*trans* form. The following thermal steps lead to the release of the retinal from the protein. Photoactivation of rhodopsin leads to interaction with a heterotrimeric guanine nucleotide-binding protein (G-protein) on the intracellular side of the membrane. The activated G-protein then triggers the further steps that ultimately lead to the hyperpolarization of the plasma membrane that initiates a nerve impulse. In its seven-helix structure and embedded ligand, rhodopsin is believed to be representative of G-protein-coupled receptors generally, a class which includes the signal transducers for acetylcholine, dopamine, glycoprotein hormones, and peptides.⁸ While rhodopsin is the rod cell pigment responsible for low-light vision, other retinal proteins in the cone cells are responsible for color vision. For these pigments the action spectrum is of obvious functional importance. In general, the visible spectra of rhodopsins are red shifted relative to the 440 nm absorption maximum of

protonated retinal Schiff bases in methanol. Because this bathochromic shift is due to the protein environment, it is known as the 'opsin shift'.⁹ The mechanisms by which the opsins 'tune' the chromophore has been one of the central issues in research on retinal proteins. The particularly large opsin shift in bacteriorhodopsin (to 568 nm) has made it a particularly interesting case even though it is not a visual pigment.

2 NMR STRATEGIES

Although NMR studies have also been made of fragments, here we will focus on studies of intact retinal proteins. These large integral membrane proteins are amenable to different NMR approaches depending on their manner of preparation. In solubilized form, they can be studied by solution techniques, with the caveats that the large protein-detergent complexes have relatively long rotational correlation times and that functional integrity cannot be assayed in the absence of a membrane. For membrane preparations, solid state techniques are required and have the potential of providing additional information from anisotropic interactions. In the crystalline native membrane, bacteriorhodopsin does not diffuse, which is ideal for solid state spectroscopy. With the exception of a few initial studies of lyophilized samples, purple membranes are normally studied as wet ultracentrifuge pellets which are frozen as needed to trap photointermediates (see below) or improve the signal-to-noise ratio. Rhodopsin, reconstituted in lipids after purification, undergoes slow rotational diffusion about an axis perpendicular to the plane of the bilayer. Since such motion interferes with cross polarization and decoupling, it is quenched for solid state NMR studies by lyophilization or freezing.

The large size of these systems makes selective isotopic labeling essential. For studies of the chromophore, the native retinal can be replaced by a synthetic isotopomer:¹⁰ the sample is bleached by treatment with hydroxylamine (which breaks the Schiff base linkage and releases retinal oxime) and then the pigment is regenerated by incubation of the sample with synthetic retinal in the appropriate conformation. Labeling of the opsins relies on bacterial or in vitro expression systems. In the case of bacteriorhodopsin, biosynthetic labeling is practical for those amino acids that the *Halobacteria* do not synthesize in excess. Attempts to isolate auxotrophic strains for the other amino acids have been successful only for arginine.¹¹ In one NMR study, an auxotroph of *Escherichia coli* was used to express selectively labeled bacteriorhodopsin, which was then purified and reconstituted in lipids.¹² So far, in vitro expression of bacteriorhodopsin¹³ has not been achieved on a scale relevant for NMR. For rhodopsin, it has so far proved impossible to prepare NMR quantities of properly folded protein either in cultures or in vitro. NMR studies of rhodopsin have therefore been restricted to the chromophore, with the exception of a recent study of a labeled fragment of G-protein bound to rhodopsin.¹⁴

For the most part, isotopic labeling of retinal proteins has taken the form of selective enrichment of naturally rare isotopes. This has the advantage of minimizing perturbation of the molecule. Thus, most NMR studies have made use of selective substitution of ¹³C for ¹²C, ¹⁵N for ¹⁴N, and ²H for ¹H. However, NMR nuclei have occasionally been

Figure 3 Photoproducts of bovine rhodopsin and their wavelengths of maximum visible absorbance. The chromophore is isomerized from 11-*cis* to all-*trans* in the initial photoreaction. Metarhodopsin II is the form that activates the G-protein. The isomerized chromophore is subsequently released and recycled by the cell

introduced less conservatively, by substitution of ^{19}F for ^1H .¹⁵ Most studies up to this point have made use of dilute spin systems; however, increasing attention is now being given to measurements of dipolar interactions between spin pairs to obtain internuclear distances. In ^{13}C studies the large natural-abundance signal generally makes the spectrum difficult to interpret, even with selective isotopic enrichment. Thus, in ^{13}C studies, it has become routine to subtract the spectrum of a natural-abundance sample from the spectrum of the labeled sample obtained under the same conditions (particularly spinning speed).¹⁶

In order to understand the molecular mechanisms of light transduction in retinal proteins, it is necessary to study their photointermediates. Time-resolved NMR studies have not been possible because of the very high optical density of the large samples required. Thus, NMR studies of photointermediates have relied on cryotrapping. In bacteriorhodopsin, pure bR₅₆₈ obtained by light adaptation can be stabilized for the duration of an NMR experiment by cooling to -5°C . The only intermediates of the bR₅₆₈ photocycle that have so far proven accessible are one of the M-intermediates and the N-intermediate. The M-intermediate is trapped alone in guanidinium hydrochloride at pH 10, which slows the M to N transition of the photocycle. These conditions are justified by the fact that the proton pump, which is the focus of interest, still functions, albeit relatively slowly. In NaCl at pH 10, the N-intermediate accumulates along with the M-intermediate. In both of these preparations, cooling to -40°C suffices to stabilize the intermediates for the duration of an NMR experiment. In rhodopsin, NMR studies have been conducted on the bathorhodopsin¹⁷ and metarhodopsin II¹⁸ intermediates, by cooling below 120 and 130 K, respectively.

3 STRUCTURE

3.1 Chromophore

In the earliest studies, retinal conformations were determined by analysis after chemical extraction. Although this procedure is relatively safe for the C=C configurations, it is not useful for single bonds, which are free to rotate when the chromophore is liberated from its binding pocket. It is also not useful for the C=N bond, which is broken on extraction. In situ studies have made use of resonance Raman spectroscopy and NMR spectroscopy. Of these, NMR has the advantage of avoiding any possible perturbation by light.

Initial NMR studies made use of the sensitivity of ^{13}C chemical shifts to steric interactions of directly bonded protons: electron density driven from the proton produces a low-frequency shift at the carbon. This effect was first identified for a retinal pigment in [12- ^{13}C] retinal-labeled bacteriorhodopsin. In the dark-adapted state, the spectrum showed a doublet with a low-frequency:high-frequency stoichiometry similar to the accepted 60:40 stoichiometry of bR₅₅₅:bR₅₆₈.¹⁹ Upon light adaptation to form pure bR₅₆₈, the low-frequency signal disappeared, confirming the assignment of signals originally made by stoichiometry.²⁰ These observations supported previous evidence for 13-*cis* and all-*trans* chromophores in bR₅₅₅ and bR₅₆₈, respectively. However, a doublet with similar

stoichiometry was also seen in dark-adapted [14- ^{13}C]retinal-labeled bacteriorhodopsin.²¹ Again, the low-frequency signal disappeared on light adaptation.²⁰ These observations suggested that the chromophores of bR₅₅₅ and bR₅₆₈ are 13-*cis*,15-*syn* and all-*trans*,15-*anti*, respectively. According to this interpretation, a corresponding steric effect should also be seen at C- ϵ of Lys216. These expectations have recently been confirmed in studies of [ϵ - ^{13}C]Lys-labeled bacteriorhodopsin, with a doublet in the dark-adapted state and disappearance of the low-frequency signal on light adaptation.²² Although the chemical shift data are thoroughly self-consistent, the most unambiguous determination of the C=N configuration has been made by rotational resonance studies of [14- ^{13}C]retinal,[ϵ - ^{13}C]Lys-labeled bacteriorhodopsin. The rate of magnetization exchange between the two carbons indicated an internuclear distance of 0.3 ± 0.02 nm in bR₅₅₅ and 0.41 ± 0.03 nm in bR₅₆₈, as expected for C=N *syn* and *anti* configurations, respectively.²³ This spin pair has also been revisited recently in a 2D rf-driven recoupling (RFDR) experiment in which the interactions can be observed in bR₅₅₅ and bR₅₆₈ simultaneously.²⁴ In this case, the more rapid development of cross-peak intensity for the low-frequency signals clearly demonstrates that these are associated with the shorter internuclear distance and steric interaction.

Steric interactions also play an important role at the other end of the chromophore. Retinal in solution comprises a rapidly exchanging mixture of the skewed 6-*s-cis* and planar 6-*s-trans* conformations, with the former dominating. The planar 6-*s-trans* conformation (shown in Figure 1) has the advantage of the extended planar π -system, but it has two methyl groups in close proximity to C-8. In the skewed 6-*s-cis* conformation the planar π -system is truncated, but only one methyl group is near C-8. Since the length of the π -system is an important factor for color discrimination, the 6-*s* conformation of the bound chromophore has received considerable attention. Studies of the 6-*s-cis* and 6-*s-trans* crystal forms of retinoic acid demonstrated that the ^{13}C -5 shift is sensitive to isomerization of the 6-*s* bond, as expected given the changes in steric interactions.²⁵ Interestingly the effect is entirely in the most high-frequency tensor element which moves 20 ppm to high frequency on 6-*s-cis* to 6-*s-trans* isomerization.

In [5- ^{13}C]retinal-labeled bacteriorhodopsin, the most high-frequency and most low-frequency tensor elements were found to correspond exactly to that of 6-*s-trans*-retinoic acid, suggesting that the chromophore in bacteriorhodopsin is the 6-*s-trans* form.²⁶ (The middle tensor element will be discussed in Section 4.1.) Complementary evidence for a 6-*s-trans* conformation in bacteriorhodopsin was obtained from the ^{13}C -8 chemical shift, which is also affected by the changes in steric interactions.²⁶ Steric interactions also influence the dynamics of the methyl groups, and the ^{13}C -18 longitudinal relaxation time in bacteriorhodopsin was found to be more typical of a 6-*s-trans* chromophore than a 6-*s-cis* conformation.²⁶ More recent ^2H NMR measurements of the activation energy for threefold hopping of the C-18 methyl group are also consistent with a 6-*s-trans* chromophore and inconsistent with a 6-*s-cis* chromophore.²⁷ Again, however, the most unambiguous determination of the 6-*s* conformation has been made by rotational resonance studies of doubly labeled bacteriorhodopsin. In [8,18- ^{13}C]retinal-labeled bacteriorhodopsin, the slow rate of magnetization exchange indicated a 6-*s-trans*

Figure 4 Solid state ^{13}C MAS difference spectra obtained by subtraction of a spectrum of natural-abundance bacteriorhodopsin from spectra of $[\epsilon\text{-}^{13}\text{C}]\text{Lys}[14\text{-}^{13}\text{C}]\text{retinal}$ -labeled bacteriorhodopsin in the M-state.³¹ (a) The CP MAS difference spectrum. The ^{13}C -14 signal is to high frequency. There are two ^{13}C - ϵ signals, the stronger low-frequency signal is from the six free lysine residues. The smaller signal is from Lys216, which forms the Schiff base with the retinal. (b)–(d) The $n = 1$ rotational resonance difference spectra for magnetization exchange between $[\epsilon\text{-}^{13}\text{C}]\text{Lys216}$ and $[14\text{-}^{13}\text{C}]\text{retinal}$ at mixing times of 0.2, 5.0 and 20.0 ms, respectively

conformation²⁸ with an internuclear distance of 0.41 nm.²⁹ In $[8,16/17\text{-}^{13}\text{C}]\text{retinal}$ -labeled bacteriorhodopsin the average internuclear distance was found to be 0.33–0.35 nm, also consistent with a 6-*s-trans* conformation.²⁹

Analogous studies have been conducted of the M-state that is trapped at pH 10, in 0.3–0.5 M guanidinium hydrochloride or 0.1 M NaCl, when bR₅₆₈ is illuminated with light of wavelengths > 540 nm, at low temperatures.^{22,30,31} The ^{13}C -5 chemical shift indicates that the 6-*s* bond is still *trans*.³⁰ The ^{13}C -12 chemical shift confirms that the chromophore is 13-*cis*. The ^{13}C -14 and $[\epsilon\text{-}^{13}\text{C}]\text{Lys216}$ chemical shifts indicate that the Schiff base configuration is still *anti*.^{22,30} This was confirmed by rotational resonance (Figures 4 and 5), which gave a 14- ϵ internuclear distance of 0.39 ± 0.01 nm, as expected for a C=N *anti* configuration and 0.1 nm larger than expected for a *syn* configuration.³¹ These results are consistent with interpretations made of resonance Raman spectra.³²

Similar studies have been made of the N-intermediate, cryotrapped with the M-intermediate in 0.1 M NaCl at pH

Figure 5 The observed and simulated magnetization exchange between $[\epsilon\text{-}^{13}\text{C}]\text{Lys216}$ and $[14\text{-}^{13}\text{C}]\text{retinal}$ in the M-state, under the $n = 1$ rotational resonance condition.³¹ - - -, 0.38 nm; —, 0.39 nm; — · —, 0.40 nm

10.³³ The 6-*s* conformation was not investigated, but the ^{13}C -12 chemical shift showed that the chromophore is still 13-*cis*, and the ^{13}C -14 and $[\epsilon\text{-}^{13}\text{C}]\text{Lys216}$ chemical shifts showed that the Schiff base remains in the C=N *anti* configuration. These results agree with the conclusions of time-resolved resonance Raman studies of the N-intermediate at room temperature.³⁴

Carbon-13 chemical shifts have also been used to characterize the rhodopsin chromophore. As in bacteriorhodopsin, the ^{13}C -14 chemical shift indicates that the Schiff base is C=N *anti* in rhodopsin³⁵ and bathorhodopsin.¹⁷ Whereas the bacteriorhodopsin chromophore has been found to be 6-*s-trans*, a 6-*s-cis* conformation is indicated by the ^{13}C -5 chemical shift in rhodopsin,^{35–37} and the ^{13}C -8 chemical shift in bathorhodopsin.¹⁷ Other ^{13}C chemical shifts are generally similar to those in the corresponding retinal Schiff base model compounds (11-*cis* for rhodopsin and all-*trans* for bathorhodopsin). Interestingly, those deviations that are observed are localized in the region of the chromophore that was identified in retinal analog studies as interacting with a protein charge.^{17,36,37} Perturbations in this region have also been detected by ^{19}F NMR of rhodopsin-containing fluorinated retinals.¹⁵

While bond isomerization determines the orientations of different parts of the chromophore relative to each other, it is also important to determine absolute orientations, especially for vectorial transport. Ulrich et al.³⁸ have used the quadrupole splittings of ^2H labels in uniaxially oriented films of bacteriorhodopsin to examine the orientation of the ionone ring relative to the membrane normal. Using the ^{31}P NMR spectral line-shape to determine the mosaic spread of the sample, and treating the ionone ring as a rigid unit, ^2H spectral lineshapes of oriented $[2,4,4,16,16,16,17,17,17,18,18\text{-}^2\text{H}_{11}]$ retinal-labeled bacteriorhodopsin, at various inclinations to the magnetic field,

were simulated for various ionone ring orientations. The fit to the experimental series of ^2H spectra was optimal for an ionone ring orientation that places the methyl groups on C-16, C-17, and C-18 at angles of 94, 75, and 46° , respectively, relative to the membrane normal. Given the known tilt of the chromophore, with the Schiff base closer to the cytoplasmic side and the ionone ring closer to the extracellular side, the ^2H analysis indicates that the C-18 methyl group points toward the cytoplasmic side of the membrane. This means that, for a fully planar all-*trans*,15-*anti* or 13-*cis*,15-*syn* chromophore the Schiff base proton or lone pair points toward the extracellular surface (as found for bR₅₆₈ in linear dichroism experiments³⁹), while for a fully planar 13-*cis*,15-*anti* chromophore the Schiff base proton or lone pair points toward the cytoplasmic surface.

3.2 Protein

Isotopic labeling of the opsin in NMR quantities has so far only been possible for bacteriorhodopsin. In this system, both secondary structure and tertiary structure have been addressed in a variety of ways.

The peptide backbone was first labeled by Lewis et al.,⁴⁰ in the carbonyls of the leucine residues, because these hydrophobic residues were expected to be buried in the membrane on the basis of their location in the hydrophobic stretches of the peptide sequence that were expected to form the transmembrane segments. The spectrum of intact [$1\text{-}^{13}\text{C}$]Leu-labeled purple membrane showed a rigid-lattice carbonyl powder pattern which indicated that, at the Leu residues, the peptide backbone was immobile on the ^{13}C NMR timescale even at 40°C . When the labeled bacteriorhodopsin was solubilized and reconstituted in DMPC (dimyristoyl phosphatidylcholine) vesicles above the lipid phase transition temperature, the spectrum was narrowed by fast rotational diffusion. Analysis of the motionally averaged lineshape was used to determine the possible orientations of the Leu peptide bonds relative to the diffusion axis. The data were found to be consistent with α_1 helices tilted at 20° from the membrane normal, a model that is congruent with electron density information.²

Bowers and Oldfield⁴¹ also studied [$1\text{-}^{13}\text{C}$]Leu-labeled purple membrane, and found a mobile component. Mobile components were also found for purple membranes $1\text{-}^{13}\text{C}$ labeled in Gly, Ile, Lys, Phe, and Val residues. For each amino acid except Val, the proportion of mobile residues was correlated with the proportion of residues in the C-terminus, suggesting that the C-terminus is mobile on the ^{13}C NMR timescale. Since the C-terminus does not contain any Val residues, it was suggested that the observation of mobile Val residues indicates another mobile region in protein. The discrepancy between these results for Leu and those of Lewis et al., described above, has not been solved.

Helgersson et al.⁴² have considered the chemical shifts of peptide carbonyl atoms. Based on homopolymers, in which the carbonyl carbon resonance is found at 176 ± 1 ppm for helical structures and 171 ± 1.5 ppm for nonhelical structures, they concluded that about 85% of Leu, 75% of Val, and 80% of Lys residues in bacteriorhodopsin are in helical regions. Less quantitatively, but more generally, Engelhard et al.⁴³ have noted that the chemical shift of the peak of the natural-abundance peptide signal in bacteriorhodopsin suggests a largely α -helical secondary structure. These results are consistent with the electron density distribution in bacteriorhodopsin.²

Seigneuret and co-workers have labeled the peptide backbone at the carbonyl carbons of the Phe⁴⁴ and Met⁴⁵ residues. Narrow, well-resolved signals were obtained by solubilizing in *n*-dodecylmaltoside. For the [$1\text{-}^{13}\text{C}$]Met-labeled bacteriorhodopsin, sequence specific assignments were obtained by selective colabeling of neighboring amino acid residues with ^{15}N and by papain proteolysis. Using these assignments, it was determined that, of the nine Met residues, only Met32, Met68, and Met163 are water exposed (as reflected in susceptibility to H_2O_2 oxidation) and weakly hydrogen bonded (as indicated by deuterium exchange from $^2\text{H}_2\text{O}$). These results are also consistent with the current structural model of bacteriorhodopsin.²

Deber et al.⁴⁶ focused on the secondary structure at proline peptide bonds, which are thought to play an important role in transport proteins. [$\gamma\text{-}^{13}\text{C}$]Pro-labeled bacteriorhodopsin was solubilized in $\text{CHCl}_3\text{:CD}_3\text{OD}$ (1:1) with 0.1 M LiClO_4 . Sufficient resolution was achieved to distinguish the 2 ppm difference in ^{13}C chemical shift between a *cis* and a *trans* X-Pro peptide bond. No *cis* signal was observed, and it was concluded that all 11 X-Pro peptide bonds in the solubilized bacteriorhodopsin are in the *trans* conformation. Further evidence has been supplied by an analogous solid state NMR study.⁴⁷ The chemical shift difference between C- β and C- γ of a proline residue is 7–11 and 3–5 ppm when the X-Pro peptide bond is *cis* and *trans*, respectively. The MAS spectrum of [$\beta,\gamma\text{-}^{13}\text{C}$]Pro-labeled bacteriorhodopsin showed only *trans*-configured X-Pro peptide bonds.

The Pro peptide bonds have also been studied by ^{15}N solid state NMR of [^{15}N]Pro-labeled purple membranes. Five well-resolved peaks are obtained at room temperature for the 11 Pro residues.⁴⁸ Less resolution is obtained at lower temperatures, suggesting that disorder is being frozen in. In order to assign the Pro91 signal, a REDOR experiment was carried out on a [$1\text{-}^{13}\text{C}$]Thr,[^{15}N]Pro-labeled sample, which has only one $^{13}\text{C}\text{--}^{15}\text{N}$ spin pair, between Thr90 and Pro91.⁴⁹ As shown in Figure 6, a single signal is obtained for Pro91 in bR₅₆₈. Figure 6 also shows a REDOR difference spectrum for a mixture of the bR₅₆₈ and M forms of bacteriorhodopsin. The spectrum clearly reveals a difference in the Pro91 ^{15}N chemical shift, providing direct evidence for a structural change in that part of the protein.

Nitrogen-15-labeled bacteriorhodopsin was also studied by heteronuclear $^1\text{H}\text{--}^{15}\text{N}$ coherence spectroscopy in methanol/chloroform (1:1) solution with 0.1 M NH_4CHO_2 .⁵⁰ In a uniformly ^{15}N -enriched sample, less than half of the cross peaks expected from the amino acid sequence were observed. By selective labeling and proteolytic cleavage, it was determined that the $^1\text{H}\text{--}^{15}\text{N}$ cross peaks were exclusively from the first two and the last helices in the sequence. Dynamic processes were inferred in the other four helices of the solubilized protein.

The protein structure has also been studied from the vantage point of the amino acid side chains. Initial studies of the mobilities of different side chains using ^2H NMR found a significant proportion of mobile residues that were attributed to surface groups.^{51–54} However, other investigations suggested that the mobile residues were largely due to contamination by residual plasma membrane.⁵⁵ More direct measures of surface exposure have made use of paramagnetic broadening in solubilized [^{13}C]methyl-labeled bacteriorhodopsin⁵⁶ and photochemically induced dynamic nuclear polarization of aromatic signals in ^1H NMR studies of solubilized natural-abundance

Figure 6 Nitrogen-15 MAS spectra for [1- ^{13}C]Thr,[^{15}N]Pro-labeled bacteriorhodopsin.⁴⁹ (a) CP MAS spectrum in the light-adapted state. (b) REDOR MAS spectrum in the light-adapted state. (c) The difference between spectra (a) and (b), showing only the signal from Pro91 (the only Pro bound to Thr) in the light-adapted state. (d) REDOR difference spectrum as in part (c) but for a mixture of the light-adapted and M states to show the change in the Pro91 chemical shift

bacteriorhodopsin.⁵⁷ Arseniev et al.⁵⁸ attempted to detect interactions between tryptophan residues in [5- ^{19}F]Trp-labeled bacteriorhodopsin solubilized in $\text{CD}_3\text{OH}/\text{CHCl}_3$ (1:1) with 0.1 M LiClO_4 . No such interactions were observed, but effects on different signals in the ^{19}F spectrum were noted upon addition of formic acid, reduction of the Schiff base, and modification of the retinal ionone ring. In similar studies of [3- ^{19}F]Phe-labeled bacteriorhodopsin, a distance of 1.3 ± 0.1 nm was measured between Phe230 and a spin label introduced at Met163.⁵⁹

4 PROTONATION AND HYDROGEN BONDING

Changes in protonation are obviously critical along the proton transport pathway in bacteriorhodopsin. As it happens, a protonation change is also at the heart of signal transduction

in rhodopsin.⁶⁰ Chemical shifts are excellent probes of protonation, and have been used to good advantage in studies of both bacteriorhodopsin and rhodopsin.

4.1 Schiff Base

Model compound studies show that chemical shifts of the odd-numbered carbon atoms of a retinal Schiff base are sensitive to the protonation of the Schiff base,²⁵ as expected based on the resonance structures which redistribute the positive charge from the Schiff base to the odd-numbered carbon atoms. The sensitivity is greatest at the C-13 position and, for rhodopsin studies which are so far limited to labels on the retinal, the ^{13}C -13 chemical shift is the clearest indicator of the protonation of the Schiff base. After some early false starts due to difficulties in replacing natural-abundance retinal with labeled retinal,^{61–63} Mateescu obtained the first ^{13}C NMR spectra for [13- ^{13}C]retinal-labeled samples of rhodopsin and bacteriorhodopsin.^{64,65} In both proteins, the ^{13}C -13 chemical shift indicated a protonated Schiff base. The ^{13}C -11 chemical shift also provided evidence for a protonated Schiff base in bacteriorhodopsin.¹⁹ In more recent work, the ^{13}C -13 and ^{13}C -15 chemical shifts obtained for bathorhodopsin are consistent with a protonated Schiff base in this photointermediate,¹⁷ and those obtained for metarhodopsin II indicate a deprotonated Schiff base in this activated state.¹⁸ In bacteriorhodopsin, the ^{13}C -13 chemical shifts correspond to a deprotonated Schiff base in the M-state³⁰ and a reprotonated Schiff base in the N-state.³³

However, the ^{15}N chemical shift of the Schiff base is by far the most sensitive probe of protonation,⁶⁶ and in bacteriorhodopsin, where it is possible to label the protein, the solid state ^{15}N NMR spectrum of [ϵ - ^{15}N]Lys-labeled bacteriorhodopsin provides the definitive determination of the protonation state of the Schiff base. Such spectra for dark-adapted bacteriorhodopsin were reported independently by Mateescu et al.⁶⁵ and by Harbison and co-workers.^{66–69} With a good signal-to-noise ratio, the spectrum shows a doublet due to the coexistence of bR₅₆₈ and bR₅₅₅ in a dark-adapted sample.^{66–69} Solid state ^{15}N NMR spectra have also been obtained for [ϵ - ^{15}N]Lys-labeled bacteriorhodopsin cryotrapped in the M- and N-states. The [ϵ - ^{15}N]Lys chemical shifts indicate that the Schiff base is deprotonated in the M-state and reprotonated in the N-state.³³

From the start, it was noted that the ^{15}N chemical shifts in bR₅₆₈ and bR₅₅₅ are still further to low frequency than normal for protonated retinal Schiff bases, and it was suggested that this is due to an unusually weak counterion.⁶⁶ Comparison of the shift tensor elements for different retinylidenebutylimine salts⁷⁰ and retinylideneanilinium salts⁷¹ has shown that the lowest-frequency element is insensitive to counterion strength, and the two high-frequency elements vary proportionately. The same relationship is observed between the tensor elements for bacteriorhodopsin, strengthening the association of the ^{15}N chemical shift with counterion strength.⁷⁰ However, the effect is more extreme in bacteriorhodopsin, indicating a counterion that is weaker than any halide, carboxylate, or phenolate moiety that might be available as a simple counterion in a protein. In order to explain the data it became necessary to postulate a complex counterion, involving water-mediated hydrogen bonding between the Schiff base and protic amino

acid residues.⁷⁰ Such a hydrogen-bonded complex would diffuse the counterion charge over several bonds. The complex counterion is consistent with the current structural model of bacteriorhodopsin, which locates water, two Asp residues and one Arg residue in the vicinity of the Schiff base.²

Interestingly, weakening the strength of the Schiff base counterion also affects the ¹³C-5 chemical shift at the other end of the polyene chain.^{71,72} In the retinylideneanilinimine salts, which crystallize in the planar 6-*s-trans* conformation, the effect shows up essentially exclusively in the middle element of the ¹³C-5 chemical shift tensor, and the unusually weak Schiff base counterion in bacteriorhodopsin completely explains the unusual value of the middle element of the ¹³C-5 chemical shift tensor in bacteriorhodopsin.⁷¹ A weak Schiff base counterion also destabilizes the ground electronic state of the chromophore relative to the excited state, and thereby constitutes an important mechanism for the bathochromic opsin shift. This effect is larger in the retinylideneanilinimine salts, which crystallize in the planar 6-*s-trans* conformation, than in the retinylidenebutylimine salts, which crystallize in the skewed 6-*s-cis* conformation.⁷¹ This enhancement is also seen in solution in 1,1-didemethylretinal Schiff bases, which adopt a planar 6-*s-trans* conformation, compared with retinal Schiff bases in which the planar 6-*s-trans* conformation is sterically disfavored.⁷² The synergistic effects of the extended π system, due to ring-chain planarization, and the weak Schiff base hydrogen bonding, due to the complex counterion, are sufficient to explain completely the very large opsin shift in bacteriorhodopsin.⁷¹

With HCl titration, the visible absorption maximum of bacteriorhodopsin shifts from 568 nm (at pH ~7) to 605 nm (at pH ~2), and then reverts to 565 nm (at pH ~0). Spectra of [ϵ -¹⁵N]Lys-labeled samples indicated that the ¹⁵N chemical shift is closely correlated with the color.⁷³ A 16 ppm low-frequency shift in the blue species indicates an even weaker Schiff base counterion than in the two purple species. This is consistent with the expected protonation of an acidic residue in the complex counterion at low pH. The recovery of the color and ¹⁵N chemical shift at still lower pH is thought to be due to the replacement of a water molecule in the complex counterion by chloride from the bulk acid. Carbon-13 NMR results for selectively enriched polyene carbons in bR₆₀₅ revealed that the chromophore conformation is generally not very different from that of bR₅₆₈, although the spectrum of [14-¹³C]retinal bR₆₀₅ showed doublets for the 15-*syn* and 15-*anti* forms that may reflect the coexistence of 13-*cis* and all-*trans* conformers in each case.⁷³

4.2 Polar Amino Acid Residues

Amino acids capable of ionization or hydrogen bonding could participate in proton transport in bacteriorhodopsin. Roles proposed for Tyr and Asp residues have motivated NMR studies of these groups.

Tyrosinate is an unusual species, but FTIR and UV studies suggested that it existed in bacteriorhodopsin. Since the [4'-¹³C]Tyr chemical shift is sensitive to deprotonation of the adjoining oxygen, it provides an unambiguous probe for long-lived tyrosinate. However, MAS NMR spectra of [4'-¹³C]Tyr-labeled bacteriorhodopsin showed no detectable long-lived tyrosinate in dark-adapted bacteriorhodopsin at pH bulk

values below 13,⁷⁴ light-adapted bacteriorhodopsin at pH = 7 or 10,⁷⁵ or the M-state at pH = 10.⁷⁵ It was concluded that the changes in Tyr residues detected by FTIR and UV spectroscopy represented changes in hydrogen bonding rather than deprotonation.

Internal Asp residues certainly do play a direct role in proton transport. Engelhard et al.⁴³ biosynthetically labeled bacteriorhodopsin with [4-¹³C]Asp. Unexpected scrambling of the label to Trp was found, but this signal causes no problem because it appears in a distinct region of the spectrum. On the other hand, the signals of the nine labeled Asp residues and the three labeled Asn residues are superimposed on peptide backbone signals due to natural-abundance ¹³C and some scrambling through the tricarboxylic acid cycle to [1-¹³C]Glu. Nevertheless, six resonances were resolved. These were considered in terms of five categories: exposed Asp residues which must be deprotonated, buried Asp residues that are not protonated, buried Asp residues that are protonated, Asn residues in polar environments, and Asn residues in nonpolar environments. The signals due to surface Asp residues were assigned to high-frequency resonances by comparison of the spectrum of the native membrane with that obtained after 'deionization' (ion exchange chromatography to replace the intrinsic cations of the purple membrane with protons). Based initially on chemical shifts and ¹⁴N line-broadening effects in model compounds, the two most narrow, lowest frequency lines were assigned to protonated Asp residues which must be buried. The protonated state of these low-frequency resonances was later confirmed by estimation of the middle chemical shift tensor element from sideband intensities.⁷⁶ Specific assignments for the Asp96 and Asp85 signals were subsequently obtained by studies of site-specific mutants.⁷⁷ By elimination, based on the current structural model of bacteriorhodopsin and FTIR studies of Asp residues, the other narrow low-frequency signal was assigned to Asp115.⁷⁶ Based on the current structural model of bacteriorhodopsin and the functional properties of site-specific mutants, Asp85 and Asp212 are expected to be influenced by light adaptation. This prediction was borne out: two signals shifted on light adaptation, including the previously assigned Asp85 signal and a signal further to high frequency which was assigned to Asp212 by elimination.⁷⁶ The signals of all four internal Asp residues have thus been assigned in bR₅₅₅ and bR₅₆₈. Using these assignments to interpret the spectrum of the M-intermediate in the D96N mutant, deprotonation of the Schiff base is seen to lead to protonation of Asp85 while Asp212 remains protonated.⁷⁸ Deionization of the membranes was also found to induce protonation of Asp85.⁷⁸

5 PROTON DIFFUSION

Among the various forms of spectroscopy that have been applied to bacteriorhodopsin, NMR has the unique potential to chart the movement of protons, which is central to the energy transduction process. One approach makes use of the relatively fast relaxation of the immobile protons of the protein.⁷⁹ In this CP MAS experiment, cross polarization is delayed until ¹H magnetization remains only in the bulk water. Under these circumstances, the only nuclei that are cross polarized effectively are those that exchange protons with bulk water on the submillisecond timescale. Using this

selection technique for [ϵ - ^{15}N]Lys-labeled bacteriorhodopsin, Harbison et al.⁷⁹ observed cross polarization of the Schiff base and the six free Lys residues, although there was no longer any cross polarization of the natural-abundance ^{15}N in the peptide backbone. By varying the delay, it was demonstrated that proton exchange between the Schiff base and bulk water is essentially complete in about 0.5 ms. Delayed cross polarization has also been applied to [^{15}N]Arg-labeled bacteriorhodopsin.^{80,81} In this case, rapid proton exchange was only observed at high pH.⁸¹

Proton NMR provides a more direct means of following proton movement. Zheng et al.⁸² have shown that high-resolution 2D ^1H MAS NMR spectra can be obtained by using ^2H to dilute and cross polarize the protons. This approach was used to obtain 2D ^1H NOESY spectra of chemically exchanging solids, and the development of cross-peak intensities was analyzed to extract the kinetic constants for exchange. Proton exchange was found to occur preferentially along hydrogen bonds. Initial 2D ^1H NOESY spectra have also been obtained for perdeuterated bacteriorhodopsin.⁸³ Signal intensity from the residual nonexchanging protons on the protein prevents detailed examination of the signals of the exchanging protons. However, the 2D spectrum shows the expected exchange among high-frequency absorbing protons and, on a somewhat longer timescale, unexpected exchange between high-frequency and low-frequency protons. The latter are believed to be water molecules in nonpolar pockets. This interpretation is supported by parallel ^2H studies of water dynamics, which show a small population of freely rotating water molecules even at very low temperatures where hydrogen bonding would inhibit rotation.⁸³ Although these experiments are the first to find evidence for water in hydrophobic regions of purple membranes, such water has been suggested to fill gaps between polar amino acids along the proton transport pathway.

1 INTRODUCTION

High-resolution NMR spectroscopy has become, alongside X-ray crystallography, one of the two most important physical methods for the study of the *structure, dynamics, interactions* and *function* of biological macromolecules—in particular proteins and nucleic acids and, to a lesser extent, polysaccharides. This article summarizes under each of these headings the general framework, the essential techniques and classical paradigms for the application of NMR in molecular biology, illustrated by the key original findings. More specialized accounts can be found under specific topics. The historical development of this field has been described in volume I of this Encyclopedia.

High-resolution NMR shares a common feature with X-ray diffraction in that both methods—in contrast to all other physical methods—permit the study of biological macromolecules at *atomic resolution*. Beyond that, the two methods are in many ways complementary. NMR offers the advantage that it allows the study of macromolecules in solution, their natural environment, while X-ray diffraction requires crystallization. Structures with molecular weights up to 37 kDa can now be determined by NMR, and the molecular weight range is likely to be soon extended upwards. Structures approaching the 1000 kDa range are already amenable to study by X-ray diffraction. Yet crystallography yields a static picture, whereas NMR provides, in addition to the structure, information on its dynamics. Such information is particularly important for the understanding of biological function. NMR is also the method of choice for the study of ligand interactions. It lends itself more easily to the determination of informative partial structures and allows estimates of ligand exchange rates, rates of structural changes in the macromolecule and observations of the modulation of macromolecular dynamics by ligand binding.

There is, however, a fundamental difference between structural information that can be derived from NMR data and that obtainable by X-ray diffraction. The experimental diffraction pattern is a simple function of geometric parameters and can be converted by Fourier transformation directly into an electron density map and hence, in principle, into a set

of coordinates. In practice, for macromolecular structures, resolution is never sufficient, and model building becomes an essential part of structure determination. On the other hand, direct transformation from data to a set of coordinates is, even in principle, impossible in NMR. Measurable NMR parameters depend simultaneously on several internuclear distances, rates of motion and rates of conformational averaging. To obtain geometric parameters (internuclear distances or angles) from a set of NMR data, it is necessary to make assumptions about the dynamics and other features of the structure. To then obtain a set of coordinates, it is necessary to search the conformational space accessible to the macromolecular chain, usually adding information not obtainable directly from NMR experiments. Both the subjective judgments required and the methods of searching conformational space are important potential sources of error. These are discussed further in the sections devoted to specific methods of structure calculation.

2 MACROMOLECULAR STRUCTURE FROM NMR DATA—GENERAL STRATEGY

Defining the structure and dynamics of a biological macromolecule (protein or nucleic acid fragment) from NMR data requires four steps: (1) experimental *resolution* and (2) *assignment* of the macromolecular spectrum; (3) *interpretation* of the observed spectra in terms of *geometric parameters* and their changes in time; and (4) *structure calculation or model building*, for which a variety of computer algorithms are available.

The limiting steps are usually the resolution and the assignment of the NMR spectrum. NMR spectra of a macromolecule typically consist of a few hundred to a few thousand overlapping lines. The first experimental task is then to resolve all spectral lines and to assign each spectral line to a specific nucleus in a specific residue in the sequence. For linear polymers, such as proteins and nucleic acids (with few exceptions), the task has become manageable. The situation for polysaccharides, where branching is frequent, is more complicated, and the assignment problem has not been completely solved.

The geometric parameters necessary for building models of a macromolecular structure are¹ estimates of internuclear distances, derived from relaxation parameters, in particular from the Nuclear Overhauser Effect (NOE)² estimates of dihedral angles, derived from coupling constants, and auxiliary constraints,³ which can sometimes be derived from chemical shifts (e.g. ring current shifts in nucleic acids, characteristic shifts in α -helices), proton exchange rates (slow rates are often taken to be indicative of hydrogen bonding), or other spectroscopic measurements. NMR spectroscopic data are by themselves never sufficient to define a macromolecular structure. Any structural interpretation of NMR data is, in practice, though not in principle, predicated on prior knowledge of the primary sequence of the macromolecule, of the covalent distances, chirality and bond angles within it and of the van der Waals radii of the constituent atoms.

Model building thus relies on the geometric parameters contained in the known primary structure and on the additional geometric constraints derived from NMR, which play a determining role in the definition of the three-dimensional

folding. It is the only one of the steps that has been largely automated, but it will always require considerable judgment. As will be discussed below, 'calculation' of NMR structures assumes that the structure is rigid. The extent to which this assumption applies varies from one macromolecule to another, and choosing the wrong assumption can lead to a wrong structure.

2.1 Solution Structures of Proteins

Resolution and assignment usually go hand in hand. The specific techniques that can be used at each step of an NMR structure determination differ, depending on the molecular weight of the protein. Simple, purely spectroscopic procedures for obtaining resolution and assignment, applicable to small structures (<10 kDa), break down at higher molecular weights, whereas the more elaborate isotope labeling techniques needed for larger structures are rarely needed for proteins of lower molecular weight.

2.1.1 Resolution

Sufficient resolution of protein NMR spectra to allow their interpretation in atomic detail has become possible by the development of three technologies: (1) high frequency NMR spectrometers, at 500–750 MHz for ^1H , allowing a high degree of chemical shift dispersion; (2) multidimensional (initially two-dimensional) spectroscopy, which allows further separation of lines overlapping in a one-dimensional spectrum by cross peaks to other lines representing physically interacting nuclei; and (3) isotopic spectral editing, or the simplification of protein NMR spectra by prior isotopic (^2H , ^{13}C or ^{15}N) labeling of the protein. As noted, purely spectroscopic methods [(1) and (2)] usually suffice to resolve the spectra of small proteins (<10 kDa). For larger proteins (>20 kDa), isotopic spectral editing is indispensable, and for the intermediate molecular weight range (10–20 kDa), the methodological requirements depend on the extent of overlap of spectral lines, which in turn depends on the specific structure.

The contributions of each of the three technologies to the resolution of protein spectra are best illustrated graphically. Figure 1 compares the one-dimensional spectra of ribonuclease at 40 MHz¹ and 750 MHz. Figure 2 shows the relationship between two-, three-, and four-dimensional spectra.² Figure 3 illustrates the simplification of a two-dimensional proton spectrum by selective deuteration³ and Figure 4 shows the two-dimensional resolution of an overlapping ^1H spectrum by adding a heteronuclear dimension through ^{15}N labeling.⁴ Many multidimensional and isotopic spectral editing schemes are now available. Inasmuch as they not only improve resolution but also allow different assignment strategies, they are discussed below under assignment.

2.1.2 Assignment. Sequential Assignment Methods

The basic idea underlying all *sequential assignment methods* is to establish a connectivity between the spectrum of an amino acid residue with that of its sequential neighbors. Two types of connectivities are generally observable in NMR spectra: (1) through-bond connectivity reflected in spin–spin coupling, possible only between covalently linked atoms;

Figure 1 (a) Ribonuclease spectra taken at 40 MHz. (Reproduced from M. Saunders, A. Wishnia and J. G. Kirkwood, *J. Am. Chem. Soc.*, 1957, **79**, 3289). (b) Ribonuclease spectra (2 mmol double-labeled RNase in 90% $\text{H}_2\text{O}/10\%$ D_2O , ^1H NOESY, 16 scans) taken at 750 MHz. (Courtesy of Bruker Instruments, Inc.)

and (2) through-space connectivity reflected in relaxation parameters—in particular the NOE, i.e. the connectivity between any two atoms in spatial proximity. Either can be used for sequential assignment, and different assignment strategies now use different combinations of either or both. The classical paradigm for sequential assignment emerged gradually. The use of coupling constants to identify amino acid residues in peptides by residue type was introduced in 1957 in the very first systematic study of amino acid and peptide spectra by Takeda and Jardetzky.⁵ The use of relaxation parameters to evaluate distances in macromolecules was first suggested in 1964.⁶ The usefulness of the combination was first demonstrated in 1976 by Gibbons⁷ on one-dimensional (1D) spectra of the cyclic peptide, gramicidin S. In this paradigm the peptide NH of each residue is identified by its (small, $J \leq 10$ Hz) coupling to the α -CH of the same residue, and the connectivity between the NH group of residue i and the NH and α -CH groups of residue $i \pm 1$ by a NOE. This 'jumps' the peptide bond, across which spin–spin coupling is too small to be useful, with the help of a relaxation parameter. In this manner, it is, in principle, possible to assign the entire spectrum of a protein, beginning with a residue

Figure 2 Illustration of relationships between heteronuclear $^{15}\text{N}/^{13}\text{C}$ -edited two-, three-, and four-dimensional (^{13}C or ^{15}N) NOESY spectra. (Modified from Clore and Gronenborn²)

whose assignment is easily established (e.g. an N- or C-terminal, or with a unique residue in a protein) and then sequentially tracing all connectivities along the polypeptide chain. The Gibbons paradigm is illustrated in Figure 5. The tracing is much more easily done in 2D spectra, where the connectivities are seen directly as cross peaks in the spectrum. Two types of 2D spectra are required as a minimum for this purpose: a COSY-type spectrum to establish through-bond connectivities, thereby at least identifying the side chains; and a NOESY-type spectrum to establish through-space connectivities. For peptides and small proteins studied at 500–600 MHz, stumbling blocks are rare, and a complete assignment of the ^1H spectrum using this paradigm can, as a rule, be obtained. Since other characteristics distances can be defined for specific types of secondary structure (e.g., for the $\text{NH } i \rightarrow \text{NH } i + 3$ for α -helices, or $\text{NH } i \rightarrow \text{NH } i + 2$ for β -sheets), the assignment procedure simultaneously yields the secondary structure pattern of the protein.

Although the paradigm is applicable, in principle, to any polypeptide chain regardless of length, practical limitations preclude its use for larger proteins. For structures larger than 10 kDa the overlap makes it difficult to distinguish between different sequential assignment possibilities and, in addition, at higher molecular weights (15–20 kDa) line broadening is

Figure 3 Comparison of the aliphatic region of (a) the natural abundance or wild-type *trp*-repressor DQF (double quantum filtered) COSY spectrum with (b) the spectrum of selectively deuterated *trp*-repressor analog (A5). (Reproduced from C. H. Arrowsmith, L. Treat Clemons, L. Szilágyi, R. Pachter and O. Jardetzky, *Makromol. Chem., Macromol. Symp.*, 1990, **34**, 33)

usually sufficient to obliterate most $\text{NH}-\alpha\text{-CH}$ couplings. A scheme based entirely on NOEs along the peptide chain and a combination of coupling constants and NOEs within side chains can sometimes be used instead.⁸ However, for unedited spectra the usefulness of this technique is still limited by overlap: increasing overlap with increasing molecular weight leads to exponentially growing ambiguities in following the sequence. Therefore, for larger molecules, isotopic spectral editing is required for both resolution and assignment.

Isotopic Spectral Editing in its simplest form, as proposed by us in 1965, is achieved by selective deuteration. Biosynthesis of proteins from a mixture of deuterated and protonated amino acids allows the preparation of a series of labeled

Figure 4 (a) Two-dimensional homonuclear spectrum of *trp*-repressor. (b) The ^{15}N -labeled HMQC spectrum of the same region of the *trp*-repressor

Figure 5 Gibbons's paradigm: magnetization transfer pathways and scalar connectivities in the peptide backbone. Arrows denote distances from the amide proton that can be defined. (Reproduced from O. Jardetzky, A. Lane, J.-F. Lefèvre, O. Lichtarge, B. Hayes-Roth, and B. Buchanan, in 'NMR in the Life Sciences', eds. E. M. Bradbury and C. Nicolini, Plenum, New York, 1986, pp. 49–72)

analogues in which only the desired combinations of amino acids remain visible to ^1H spectroscopy. Even though the labeling is by residue type (e.g. all leucines protonated, or all isoleucines deuterated), this type of editing reduces the problems of overlap sufficiently to allow, by itself, complete sequential assignment in larger proteins. Its largest drawback is the expense of preparing a sufficient number of deuterated analogues. Selective deuteration also narrows the linewidths by reducing the number of interacting neighbors and hence the number of alternative pathways for magnetization transfer or 'spin diffusion'. This may in some cases allow the observation of coupling constants not observable in a fully protonated

species and the use of such constants for sequential assignment. In other cases, however, line broadening by the nearest neighbor will be sufficient to limit the assignment options to those relying on through-space (NOE) connectivities.

Heteronuclear spectral editing schemes for resolution and assignment using multidimensional spectroscopy based on uniform ^{15}N or combined ^{15}N and ^{13}C labeling have been devised, and their usefulness for assigning the spectra of proteins in the intermediate molecular weight range (20–30 kDa) has been demonstrated. The simplest among these are heteronuclear three-dimensional 3D HMQC (heteronuclear multiple quantum coherence)-NOESY or HSQC (heteronuclear single quantum coherence)-NOESY experiments on uniformly ^{15}N labeled peptide chains. In this experiment, the backbone NH resonances are spread out in two dimensions (^1H and ^{15}N) and their connectivities to each other and to their respective side chains are established by a NOESY experiment in an additional (^1H) dimension. In favorable cases the overlap is reduced sufficiently to allow a complete, or nearly complete, set of sequential assignments needed for a structure determination. At higher molecular weights, however, this is not always sufficient to eliminate overlap, and selective labeling becomes necessary.

A very general triple-resonance sequential assignment strategy based on ^{13}C and ^{15}N double labeling of the peptide chain has been developed.^{9,10} The connectivities that can be established using this strategy, and the 3D experiments required for this purpose are summarized in Figure 6.^{9,11} The crucial interresidue connectivity bridging the peptide bond can be obtained in several different ways, relying on each of the following correlations: (1) HNCO relying on the across-the-amide bond ^{13}CO – ^{15}N coupling $J(\text{NCO}) \approx 15$ Hz; (2) HNCA identifying each NH with the $\text{C}\alpha$ of its side chain by the ^{15}N – $^{13}\text{C}\alpha$ coupling constant $J(\text{NC}\alpha) \approx 7$ – 11 Hz; (3) HCACO identifying each carbonyl with the $\text{C}\alpha$ of its side chain by the large $^{13}\text{C}\alpha$ – ^{13}CO coupling constant $J(\text{C}\alpha\text{CO}) \approx 55$ Hz; (4) ^{15}N HOHAHA-HMQC providing the same identification of the ^{15}NH group with its side chain as (2), but relying on proton couplings, $J(\text{NC}\alpha\text{H}) \approx 5$ – 10 Hz; and (5) HCA(CO)N, again bridging the peptide bond using the two-bond $^{13}\text{C}\alpha(i+1)$ – $^{15}\text{N}(i)$ constant $J(\text{C}\alpha\text{N}) \leq 7$ Hz.

Additional and alternative correlation pathways for the triple resonance correlations can also be defined, and the technique has been successfully used to establish the structures of calmodulin and of its complex with a 2 kDa calmodulin receptor binding domain (16.7 kDa; 19.4 kDa in the complex),¹² the ribonuclease domain of HIV-reverse transcriptase (18 kDa),¹³ *Escherichia coli* enzyme III(glc) (18.1 kDa),¹⁴ and human interleukin-4 (15.4 kDa).¹⁵ The details of these and many other possible similar experiments are described in more detail elsewhere in this Encyclopedia. Although they are very useful extensions of the existing technology for the study of intermediate-size proteins (up to 30 kDa), as a class the heteronuclear multidimensional assignment strategies do not escape the problems posed by increasing molecular weight, for two reasons. First, they require relatively long pulse sequences, which lower the sensitivity of the NMR experiment, and as the T_2 becomes shorter with increasing molecular weight, this effect becomes more prominent. Second, they rely on heteronuclear coupling constants of the order of 10–15 Hz, and in a fully protonated protein at molecular weights above the range 30–40 kDa most of these will be obliterated by line

Figure 6 Connectivities observed in the five different types of three-dimensional NMR experiments. (a) The HNCO experiment correlates the peptide bond C' and ^{15}N resonances with the NH chemical shift. (b) The HNCA experiment correlates the NH and ^{15}N shifts with the intrasidue $\text{C}-\alpha$ shift. For $\approx 60\%$ of the residues in calmodulin, a two-bond connectivity to the $\text{C}-\alpha$ resonance of the preceding residue is also observed (broken line). (c) The HCACO experiment correlates intrasidue $\text{H}-\alpha$, $\text{C}-\alpha$, and C' chemical shifts. (d) The ^{15}N HOHAHA-HMQC experiment correlates intrasidue ^{15}N , NH and $\text{H}-\alpha$ shifts. (e) The HCA(CO)N experiment correlates the $\text{H}-\alpha$ and $\text{C}-\alpha$ shifts of one residue with the ^{15}N shift of the next residue. (Reproduced from M. Ikura, L. E. Kay and A. Bax, *Biochemistry*, 1990, **29**, 4659)

broadening. Their usefulness can be extended by combination with selective deuteration, and the combination has been used successfully in the determination of the structure of the *trp*-repressor–DNA complex (37 kDa).¹⁶ It can be expected that the very significant reduction of the relaxation rate in selectively deuterated proteins will allow even further extension of the usefulness of the combined homo/heteronuclear labeling methods to achieve complete resolution and assignment for

proteins of still higher molecular weight. At the time of writing, the potential of the combined isotope editing techniques has not yet been fully realized. A more detailed discussion of the possibilities and limitations is available.¹⁷

2.1.3 Interpretation of NMR Data to Obtain Geometric Constraints

The conversion of the experimentally observed parameters (mostly intensities of cross peaks in multidimensional spectra) into geometric parameters that can be used for structure calculation (i.e. internuclear distances and dihedral angles) requires a series of subjective judgments.

The simplest model for obtaining a distance from cross peak intensities in a NOESY spectrum is the well known and widely used ‘two-spin approximation’, relating the observed cross-peak intensity (in this case equal to the cross-relaxation rate) to a single internuclear distance, r :

$$\sigma = \frac{K\tau}{r^6} \quad (1a)$$

where K is a constant and τ is the single (rigid body) correlation time. This equation holds *approximately* for small structures observed at short mixing times. For larger structures (above 15 kDa), equation (1a) does not hold even approximately. Even in the simplest case there exists an uncertainty in the relationship between distance and peak intensity, because the value of τ (the local correlation time of the internuclear vector in question) is unknown. The most commonly made assumption is that the macromolecule is rigid and that the overall rotational tumbling time can be used for all internuclear vectors. As noted, this assumption has proved very useful as a first approximation, even though it generally does not hold. The reason for the success of the assumption, even in some cases where its applicability is doubtful, is that the sixth-power relationship between peak intensity or correlation time and distance substantially reduces the error in the distance that results from an erroneous estimate of either peak intensity or correlation time: an error of a factor of 10 in either of the latter results in only a 46% error in the estimated distance. For the determination of the overall topology such errors can be tolerated. To account for them, as well as for the experimental errors of intensity measurements, it is customary to interpret each observed NOE not in terms of a single distance, but in terms of a distance range. A commonly used classification is into ranges allowed for ‘strong’, ‘medium’, and ‘weak’ NOEs. Many different calibrations of appropriate distance ranges, some differentiating between ‘very strong’ and ‘strong’, and ‘weak’ and ‘very weak’, have now been carried out. It can be said that for the first structure calculation, the differences between them are not significant. A set of typical values is given in Table 1, and the issues are discussed in more detail elsewhere.^{18,19}

Some workers have attempted to reduce the uncertainties of relating observed intensities to distance by using an empirical calibration in the form:

$$r_u^6 = \frac{(\text{NOE})_k}{(\text{NOE})_u} \cdot r_k^6 \quad (1b)$$

where $(\text{NOE})_u$ is the intensity of the NOE for the spin pair at an unknown distance, r_u , and $(\text{NOE})_k$ is the NOE intensity

Table 1 Distance between Residues as Determined by NOE Intensity

NOE Intensity	Distance Range (nm)
Strong	0.18–0.27
Medium	0.18–0.33
Weak	0.18–0.50
Very Weak	0.30–0.60

for a spin pair for which the distance r_k is known. However, the use of this calibration implies strictly that the molecule is rigid and that the two-spin approximation applies. Use of distance *ranges* is equivalent to loosening these constraints in order to take the reality of internal flexibility in proteins at least partially into account. The precision of a calibration is therefore deceptive. Given that differences in local correlation times and the limits of the applicability of equation (1a) are now well known, it is doubtful that distances derived by calibration can be considered accurate. Better accuracy is still achieved by using a reasonable estimate of the allowed distance ranges.

A more significant source of error is the fact that equation (1a) does not hold, except for small structures and mixing times that are too short to obtain good spectra on larger molecules. Under these conditions one must take into account that magnetization transfer during the experiment is not limited to the two spins, but occurs between all neighboring spins in the structure. This phenomenon is known as spin diffusion, and the evolution of magnetization (peak intensity) in the presence of spin diffusion is given by the generalized Bloch equations:

$$\frac{dM_i}{dt} = -\rho_i[M_i - M_i(0)] - \sum_{j \neq i} \sigma_{ij}[M_j - M_j(0)]; i \neq j \quad (2)$$

where ρ_i is the spin–lattice relaxation rate of the i th nucleus, and σ_{ij} is the cross-relaxation rate between the two nuclei i and j , as defined in equation (1a).

To solve the generalized Bloch equations, one obviously has to know already the structure that one is trying to determine. The initial structure calculation therefore *always* has to rely on the assumption that equation (1a) holds as a first approximation. To compensate for the additional (and often substantial) errors resulting from spin diffusion, it is necessary to widen the limits for the distance estimates for purposes of the initial calculations on larger molecules. The effects (and errors) due to spin diffusion can be greatly reduced by selective deuteration of the protein, as noted above. The ultimate molecular weight limit for structure determination by NMR remains to be explored, but given the dramatic reduction of linewidths by selective deuteration, probably lies much higher than originally expected. Good local spectra have now been obtained for structures as large as 150 kDa.²⁰ It must be noted that using the solution of equation (2), or of its equivalent, the relaxation matrix equation for the back-calculation of spectra from an initial structure again usually involves the assumption that the structure is rigid and a single correlation time can be used in the structure calculation. Back-calculation based on this assumption may not significantly increase the accuracy of the structure over the crude initial model—as discussed below. The important point to bear in mind is that the geometric parameters derived from

NMR experiments are always approximate, and the quality of the approximations used is an important determinant of the accuracy of the resulting structure.

The magnitude of the errors that can be introduced by neglecting spin diffusion can be well illustrated by an early model calculation on sperm whale myoglobin.¹⁸ Distances derived from the X-ray structure and a correlation time of 8 ns were used to calculate cross-peak intensities by solving the generalized Bloch equations [equation (2)]. These intensities were then analyzed using equation (1a) and the same correlation time to estimate (apparent) ‘NOE distances’. A plot of the apparent distances versus actual crystallographic distances (Figure 7),¹⁸ indicates that the error in the distances calculated from equation (1a) depends on the details of the surrounding structure and may be as high as $\pm 50\%$ for distances >0.3 nm. Very precise distance calibrations of NOEs on an unknown structure [equation (1a) or equation (1b)] are apt to introduce significant distortions into the calculated structure.²¹

The dihedral angles, which can be derived from coupling constants in COSY-type spectra and used to define the conformations of both the protein backbone and of the side chains, are subject to similar uncertainties. In the presence of free rotation around side-chain bonds, the observed values

Figure 7 Apparent ^1H – ^1H distances calculated from NOEs (r_{NMR}) plotted versus actual crystallographic distances (r_c) for helix 4 of myoglobin. NOE cut-off: 2%. (●) Intramolecular distances; (○) intermolecular distances. (Reproduced from O. Jardetzky and A. N. Lane, in ‘Physics of NMR Spectroscopy in Biology and Medicine,’ ed. B. Maraviglia, Italian Physical Society, North-Holland, Amsterdam, 1988, pp. 267–301)

are averages over several conformations and do not permit a unique interpretation. Dihedral angles are most useful along the backbone, where the rotation is hindered, and stereospecific assignments, e.g. those of individual methylene protons, β -CH' and CH'', are possible. In that case, a unique value of the angle (more precisely, a narrow range of angles allowed by the coupling constant) can often be derived from the Karplus relation.²² Since the coupling constant has a strong dependence on the dihedral angle, experimentally derived angles are powerful constraints in a structure calculation. The largest limitation to their use is the fact that the small coupling constants involved (often <10–15 Hz) become largely unresolvable at molecular weights above 15 kDa. For larger molecules, only broad ranges of dihedral angles, inferred from indirect evidence on the secondary structure, can be used (as relatively loose constraints) in the structure calculation.

It is still best to make the choice of assumptions explicitly, on the basis of prior experience and with additional knowledge of the specific system on which the structure is to be determined, although there is an increasing tendency to make them implicitly in an iterative back-calculation of spectral intensities using one of the several computer programs available for this purpose. The danger of such implicit decision-making is that each program has specific assumptions built into it, of which the user may or may not be aware. Almost all programs are built on the assumption that the protein is rigid (or undergoes only averaging of the first kind, i.e. in a potential well about a single energy minimum, but does not undergo any averaging of the second kind, i.e. between different metastable conformations). This assumption holds reasonably well as a zero-order approximation in many cases, especially for smaller, well chosen globular proteins, but the cases of the *trp*-repressor and several other larger proteins have clearly shown that it is not universally applicable. *There exists no general, universally applicable, set of assumptions for the exact geometric interpretation of spectroscopic parameters in macromolecular spectra.* Obviously, the calculated structure will be wrong if the assumptions made at this step are not appropriate for the molecule under study.

2.1.4 Model Building and the Calculation of Protein Structures

There are several options for defining a three-dimensional structure of a protein from the geometric constraints implied by NMR data. The basic paradigm is straightforward: given the primary sequence (with all covalent bond lengths and angles and van der Waals radii implied by it, which must be determined by other methods and known to begin with), and given a set of distance and angular constraints derived from NMR experiments, as outlined above, find the family of all three-dimensional configurations that satisfy the given set of experimental constraints. The essential step here is to search the conformational space available to the polypeptide chain, selecting only those configurations that are allowed by the NMR constraints. The first 3D structure derived from NMR data, that of the *lac*-repressor headpiece (MW $\approx$ 6 kDa) was built by hand, using Pauling-Corey space-filing models.²³ At the time of writing, several classes of search procedures have been implemented in computer programs and are generally available. A major consideration in choosing the procedure is that the search must be sufficiently representative to ascertain

that alternative configurations equally compatible with the experimental data set are included in the final result. This is more easily said than done. The conformational space available to a polypeptide chain is very large (for the two Ramachandran angles, each allowed only two values, it is of the order of 2^{2N} , where N is the number of amino acid residues in the chain; i.e. for 100 residues, it is of the order of 2^{200} or 10^{60}). A systematic search of all possible configurations is therefore computationally out of the question. Even exhaustive random sampling, starting with a variety of randomly chosen arbitrary configurations, is possible only for relatively short peptide chains (up to 10–12 kDa). Consequently, all search procedures have to rely on approximations and it remains important to ascertain that the approximations made in each applicable algorithm are valid for the specific system under investigation. The derivation of three-dimensional structures from NMR data is only possible because some of the experimental distance constraints—in particular NOE constraints between residues distant in the primary sequence (e.g. between residues 6 and 42, or 24 and 98)—at once eliminate large segments of the conformational space. Furthermore, a not very large number of imprecise constraints can define the folding of a polypeptide chain rather accurately, as originally pointed out by Kuntz and coworkers.²⁴ The human mind remains by far the most efficient instrument for recognizing and applying this hierarchy of constraints in order to reduce the search space. For this reason, model building, which had at first been all but abandoned in favor of 'more objective' search procedures that treat all constraints alike, is again gaining in importance as the molecular size of the structures being determined increases, making 'objective' random searches computationally intractable.

Among the available algorithms for searching conformational space and selecting structures compatible with the experimental constraints, it is useful to distinguish between methods that (a) rely on geometric information alone, and (b) those that bring to bear additional information on the search in the form of energy potentials. In the first category of purely geometric methods, there are three classes of algorithms: (1) computer model building, (2) distance geometry, and (3) optimal filtering. In the second category—there is one class: (4) restrained molecular dynamics (RMD). In practice, a combination of a geometric and a dynamic method²⁵ is now almost universally used, and molecular dynamics can be considered indispensable for the refinement of NMR as well as of X-ray structures. At the same time, molecular dynamics is most effective if a starting structure not very far from the final structure is provided. Only for rather small structures is it practical to fold a random polypeptide chain into its final configuration by using an RMD algorithm.

(1) *Computer model building* programs are either entirely manual (e.g. Frodo, Quanta, and MacImDad) or have a built-in routine for conformational-space searches under geometric constraints (e.g. PROTEAN). In the manual programs, the application of covalent, bond angle and van der Waals constraints is often automated, but the application of NMR-derived distance and angular constraints is under the complete control of the experimenter. Application of constraints is usually sequential, with those deemed most constraining (i.e. those connecting two structures, as in the case of protein–DNA complexes, or two distant parts of a protein chain) being applied first. Even though the procedure is subjective, it

is generally valid because all conformations violating these key constraints can be ruled out. As in all initial model building, the assumption is made that averaging between two or more distinct conformations (averaging of the second kind) does not occur. The typical result is a topologically accurate, but imprecise, model that can be used as a starting structure for refinement by RMD. In the case of constraint satisfaction programs, such as PROTEAN, which build models automatically under a given set of constraints, a *systematic* search of the space available for the mutual positioning of units of secondary structure is possible. By considering each unit of secondary structure as a rigid entity and representing it at a higher level of geometrical abstraction (e.g. cylinders for α -helices or β -strands), the number of conformational variables is reduced to a manageable size. This makes a systematic search of the conformational space available to define the main topological features (with the reduced set of key variables) computationally tractable. Since the space to be searched grows exponentially with the number of variables (e.g. rotatable bonds), systematic sampling of conformational space using the complete set of variables is otherwise only possible for very small peptides. If the output of such a systematic search, which generally defines the overall topology rather well, is used as a set of starting structures for molecular-dynamic refinement at atomic resolution, it is possible to minimize the danger of having the refined structure represent a single local minimum. This is difficult, if not impossible, when only a smaller set of starting structures is used, whether such a set is derived from manual model building or random sampling by distance geometry. Adequate sampling of random structures is at present limited to proteins smaller than ~ 12 kDa. For larger structures, random sampling that could safely be considered extensive enough is prohibitively expensive in computer time, and the danger that the reported structure represents only a local minimum remains ever present. Computer model building is hardly necessary for the smaller structures where adequate random sampling is computationally feasible. For larger structures, some degree of preliminary model building is unavoidable. A typical PROTEAN output, defining the topology of the helix–turn–helix *lac*-repressor DNA binding domain (headpiece), along with the uncertainty in the positioning of the different units of secondary structure, is shown in Figure 8.²⁶

(2) *Distance geometry* (DG)²⁷ is a general method for calculating the atomic coordinates of a structure from an arbitrary set of internal distance and/or angular constraints. It has two highly attractive characteristics: (1) it is a simple and rigorous mathematical theory containing the proof that if all the distances between all points within a structure are known precisely, an exact calculation of the coordinates of each point in the structure is possible; and (2) computational efficiency. In applications to NMR structure determination—where only a fraction of all distances that rigorously define the structure can be obtained experimentally—theoretical rigor is lost, but the efficiency of the method for randomly searching conformational space remains.

The input to a DG calculation is: the *distance matrix* derived from experiment—in principle the square matrix of $N(N - 1)/2$ distances between all N atoms (points), in practice a (usually asymmetric) matrix of the distances available from experiment; and an *initial coordinate matrix*, preferably consisting of a random arrangement of points.

Figure 8 *Lac*-Repressor headpiece structure calculated by PROTEAN, showing the uncertainty in the positioning of the different units of secondary structure. (Reproduced from R. B. Altman and O. Jardetzky, *J. Biochem.*, 1986, **100**, 1403)

This represents the ‘starting structure’ for the search of the conformational space. The first step in a DG calculation, called *embedding*, calculates a set of coordinates that represents a multidimensional best fit of the coordinates to all the distances considered simultaneously. As allowed distance ranges rather than precise distances have to be used, and because the number of observable distances is too small to define the structure precisely, the resulting structures that at first seem to satisfy the constraints in fact usually contain a large number of constraint violations—and also violate constraints at first not considered, such as van der Waals radii. A second *optimization* step is therefore necessary to minimize the errors by iterative adjustments, using a scoring function that reflects the number and severity of the violations as a criterion for the goodness of fit.

There are many different algorithms for carrying out the embedding step and many different formulations of the optimization function, a detailed description of which is beyond the scope of this article, but can be found elsewhere.²⁸ The essential mathematical features of the two steps are given by equations (3) and (4). In the first step

$$\mathbf{S} = \lambda \mathbf{M} \quad (3a)$$

where $\mathbf{S}$ is the coordinate matrix and $\mathbf{M}$ is the metric (distance) matrix, calculated from the initially set up distance matrix by a coordinate transformation to refer all distances to the geometric center of the structure which can be calculated from the distance matrix. The elements of $\mathbf{M}$ are:

$$M_{ij} = \frac{1}{2}(D_{i0}^2 + D_{j0}^2 - D_{ij}^2) \quad (3b)$$

where D_{i0} is the distance of the atom i from the origin and D_{ij} the internuclear distance between i and j . λ is the matrix of coefficients relating the two.

The embedding process itself is thus seen from equation (3a) to be an eigenvalue problem (finding the values of λ to yield the values of $\mathbf{S}$), for the solution of which a variety of techniques is available.²⁹ A typical error function useful for

Figure 9 C- α traces of a family of crambin structures computed using the distance geometry protocol. The target structure is shown in green. (Reproduced from J. C. Hoch and A. S. Stern, *J. Biomol. NMR*, 1992, 2, 535)

optimization in distance space is:

$$F_E(R) = \sum_{i < j} (|R_{ij}| - U_{ij})^2 + \sum_{k < l} (L_{kl} - |R_{kl}|)^2 \quad (4)$$

where $F_E(R)$ is the distance error, L_{ij} and U_{ij} the lower and upper distance boundaries, respectively, and R_{ij} the actual distance in the proposed structure. Similar error functions can be introduced for dihedral angles and chiral constraints (to distinguish between L- and D-amino acid configurations). The result of each calculation is a single optimized structure. Experience shows that repeated calculations with the same set of initial constraints but different starting structures do not exactly reproduce the same structure. Therefore, a family of structures is usually obtained by repeated runs of the DG algorithm. Published structure determinations report anywhere from 30 to over 100 closely related but different structures, and the precision of the structure can be measured by taking the root-mean-square deviation (RMSD) of the individual atomic coordinates. A typical family of structures calculated by repeated optimization using a DG algorithm is shown in Figure 9.³⁰

Important to note is that all non systematic search procedures contain several potential sources of bias. Among the most important in the case of DG are: (1) the algorithms used for the generation of starting structures; (2) the adequacy of their use in an individual case; and (3) the choice of weighting factors for the error function when forms more complex than equation (6) are chosen, as they now usually are. Comparisons of different programs are therefore of utmost importance, but thus far have been carried out only sporadically, as discussed below.

(3) *Optimal filtering* is a probabilistic method widely used in signal processing. Its application to the search of conformational space in the course of an NMR structure determination has the advantage that a set of coordinates, and the uncertainty limits of each coordinate, can be obtained in a single calculation from the starting set of distance and angular constraints and the estimated uncertainties of these constraints. This eliminates the need for repeated optimization runs with different starting structures and the bias potentially introduced

by limiting the calculation to an inadequate number of runs. All data relevant to the uncertainty of the final structure are introduced into the calculation and used throughout the calculation at once.

The principle of the method is to represent the system (structure) by a coordinate ‘state vector’ of length $3N$, where N is the number of atoms in the structure, and of the form:

$$\mathbf{x} = [x_1 \ y_1 \ z_1 \ x_2 \ y_2 \ z_2 \ x_3 \ y_3 \ z_3 \ \dots] \quad (5)$$

x_1, y_1, z_1 , etc., denote the x, y, z coordinates of all individual atoms. The uncertainty of the structure is contained in the covariance matrix of $\mathbf{x}$:

$$\mathbf{C}(\mathbf{x}) = \begin{bmatrix} \mathbf{C}(x_{1,1}) & \mathbf{C}(x_{1,2}) & \dots & \mathbf{C}(x_{1,N}) \\ \mathbf{C}(x_{2,1}) & \mathbf{C}(x_{2,2}) & & \\ \vdots & & \ddots & \vdots \\ \mathbf{C}(x_{N,1}) & \dots & & \mathbf{C}(x_{N,N}) \end{bmatrix} \quad (6a)$$

where

$$\mathbf{C}(x_{i,j}) = \begin{bmatrix} \sigma_{x_i x_j} & \sigma_{x_i y_j} & \sigma_{x_i z_j} \\ \sigma_{y_i x_j} & \sigma_{y_i y_j} & \sigma_{y_i z_j} \\ \sigma_{z_i x_j} & \sigma_{z_i y_j} & \sigma_{z_i z_j} \end{bmatrix} \quad (6b)$$

is the covariance matrix for an individual atom with the variance $\sigma_{xy} = E_{(xy)} - E_{(x)}E_{(y)}$ is defined as usual in terms of the expectation values. The diagonal terms of equation (6b) measure the uncertainty in each coordinate, and the off-diagonal terms determine the shape of the spatial distribution of the uncertainty. A common assumption is that this distribution is normal, in which case the uncertainty in the position is given by an ellipsoid. However, asymmetry in the uncertainty distribution of the initial constraints can be taken into account by the use of higher order moments to describe the distribution.

In the first order calculation, distance constraints are used in the form

$$z = |x_i - x_j| + v, \text{ or, generally, } z = h(\mathbf{x}) + v \quad (7)$$

where v is the uncertainty range in the measurement of the distance. A similar equation applies to angular constraints.

The constraints are introduced to update an initial structure given by an initial state vector $\mathbf{x}_0$ to a new structure that better fits the constraints by calculating a new set of coordinates from the Kalman filter formula:

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \mathbf{K}[z - h(\mathbf{x}_{\text{old}})] \quad (8)$$

where

$$\mathbf{K} = \mathbf{C}(\mathbf{x}_{\text{old}}) \mathbf{H}^T [\mathbf{H} \mathbf{C}(\mathbf{x}_{\text{old}}) \mathbf{H}^T + \mathbf{C}(v)]^{-1} \quad (9)$$

where T denotes the transpose and $\mathbf{H}$ is given by:

$$\mathbf{H} = \frac{\partial h(\mathbf{x})}{\partial \mathbf{x}} |_{\mathbf{x}_{\text{old}}} \quad (10)$$

Figure 10 Tertiary structure of the *trp*-holorepressor calculated using the Kalman filter. The α -carbon trace is displayed (at 2 SD) with ellipsoids of uncertainty for each α -carbon, the larger ellipsoids at the extreme left and right indicating the larger uncertainty for region D. (Reproduced from C. Arrowsmith, R. Pachter, R. Altman and O. Jardetzky, *Eur. J. Biochem.*, 1991, **202**, 53)

The covariance matrix $\mathbf{C}$ is updated by a formula analogous to equation ((8)). Programs have been written for either a sequential or a simultaneous introduction of constraints, and for calculations in either cartesian (PROTEAN2)³¹ or dihedral angle space (FILMAN).³² The calculation must be iterated for nonlinear systems, hence the occasionally used name, ‘Doubly Iterated Kalman Filter’ (DIKF). As in the case of DG, for small structures the initial ‘structure’ can be a random distribution of points (or all points placed at the origin) with very large initial variances. In both cases, starting structures more closely resembling the final result (and obtained by initial model building) are required for larger proteins to make the structure calculation feasible computationally. Also, in both cases, the definition of the uncertainty in the distance constraints used for the conformational space search remains subjective, as discussed in the section on the conversion of spectral intensities into distances. The topology of the *trp*-repressor backbone, determined by optimal filtering, together with the uncertainty ellipsoids of the α -carbon atoms is shown in Figure 10.³³

The model-building methods described thus far rely on purely geometric information. Because the geometric constraints derived from NMR experiments are generally imprecise and too few in number to give an exact definition of the protein structure, the resulting structures generally represent the overall topology rather well, but contain numerous energetically unfavorable, and sometimes impossible, features. For this reason, refinement of the crude structure by energy minimization is generally necessary, and molecular dynamics algorithms have become the method of choice for this purpose.

(4) *Molecular dynamics*, as a method for search of the conformational space under a given set of geometric constraints, differs from the purely geometric methods of model building, distance geometry and optimal filtering in that energy potentials, representing both attractive and repulsive interactions between atoms, are introduced into the calculation in addition to the experimental constraints.

The technique is based on the solution of Newton’s equations of motion for all atoms in the structure simultaneously:

$$\frac{\partial^2 \mathbf{r}_i}{\partial t^2} = \frac{\partial \mathbf{v}_i}{\partial t} = \frac{\nabla E(\mathbf{r}_i)}{m_i} \quad (11)$$

where $\partial^2 \mathbf{r}_i / \partial t^2$ is the acceleration and $\mathbf{v}_i$ is the velocity of atom i . This mass, m_i , of each atom is known. The force is taken to be the gradient of an empirically defined set of potentials, which is the weighted sum of all relevant terms:

$$E_{(xi)\text{empirical}} = \sum_{P=1}^N N_1 E_{\text{bond}} + w_2^P E_{\text{angle}} + w_3^P E_{\text{dihedral}} + w_4^P E_{\text{van der Waals}} + w_5^P E_{\text{electrostatic}} + w_6^P E_{\text{H bond}} \quad (12)$$

In *restrained molecular dynamics* (RMD), experimental distance and angular constraints are usually introduced as pseudopotentials of the form

$$E_{\text{NOE}} = S \frac{kT}{2d^2} (R - d)^2 \quad (13)$$

where S is a scaling factor, k is the Boltzmann constant, T is the absolute temperature, R is the averaged internuclear distance, and d is the allowed distance bounds.

The solution of Newton’s equations proceeds by numerical integration over very small time steps, Δt , over which the forces are assumed to remain constant:

$$\mathbf{r}_{n+1} = 2\mathbf{r}_n - \mathbf{r}_{n-1} - \frac{\nabla_{\mathbf{r}_n} E(\mathbf{r}_n)}{m} \Delta t^2$$

$$\mathbf{V}_n = \frac{1}{2\Delta t} (\mathbf{r}_{n+1} - \mathbf{r}_{n-1}) \quad (14)$$

This is the so-called *Verlet algorithm*. The choice of a sufficiently small time step (by comparison to the timescale of the fastest motion in the system) is critical, and values of the order of $\Delta t = 0.001$ – 0.002 ps are normally used.

A large amount of literature exists on the best choice of potentials, number of terms and weighting factors,^{34–36} and different programs incorporate sometimes very different sets of potentials. Similarly, the choice of initial velocities, usually based on a Maxwell distribution at a chosen temperature, can be made at will. Both an energy minimum and a trajectory for the motions of individual atoms over the period of the calculation can be calculated for any starting structure.

It is possible to use RMD as a purely geometric method for the search of the conformational space by assigning very high values to the pseudopotentials representing the experimental constraints and making all other potentials negligible by comparison. As in the case of DG and DIKF, the topology of small structures can be calculated successfully by starting with an arbitrary arrangement of atoms (usually given the correct covalent and bond angle constraints). As

the molecular size increases, it rapidly becomes necessary to start with a structure resembling the final result if the computational time is to be kept within manageable limits. This is much more important for RMD than for DG or DIKF calculations because of the larger number of arbitrarily adjustable parameters. The large number of adjustable parameters also makes the method subject to stronger built-in systematic bias. Fortunately, several programs have been tested extensively—notably X-PLOR, CHARMM, GROMOS and AMBER—and even though none of these are fool-proof or free of all bias, internally consistent results can be obtained in most cases. Credible refinement of NMR structures to an ‘effective resolution’, i.e. precision of 0.05 nm, is possible in many cases. This ‘resolution’ is obtained, as in the case of DG, by calculating a family of structures, each representing a complete RMD calculation beginning with a different starting structure each time, and then determining the RMSDs of the atomic coordinates within the family. Of particular interest for structure calculations using molecular dynamics is the simulated annealing protocol (sometimes even discussed as a separate method of structure calculation). In this protocol the temperature is repeatedly raised in the course of each molecular dynamics simulation, in order to reduce systematic bias by randomizing the structure, and then allowed to converge onto a new configuration. For the largest structures refined thus far (37 kDa), the computer time required for the calculation of an RMD family by this procedure can be prohibitively long. For such structures, however, it is possible to invoke the ergodic theorem (equality of the time average to the ensemble average) and use the Sequential simulated annealing protocol³⁷ to obtain a family of structures from a single calculation. A typical family of structures obtained by RMD has the same appearance as a family calculated by DG (see Figure 9).

2.1.5 Back-Calculation of NMR Spectra

Back-calculation of NMR spectra from a given structure has long been recognized as a desirable step for the validation and refinement of the proposed structure,³⁸ regardless of the method initially used to derive the structure. The back-calculation for NOESY-type spectra is based on the numerical integration of the set of generalized Bloch equations [equation (2)] or, as an equivalent, the inversion of the relaxation matrix^{37,39} using the coordinates of the proposed structure to calculate the required interproton distances.^{40,41} Several programs—including BLOCH, CORMA, IRMA, MARDIGRAS—are available for this purpose. Direct refinement of the structure against experimental NOE intensities has also been developed and implemented in X-PLOR. The use of time-averaged distances, with the averaging based on a molecular dynamics trajectory, has been suggested as an improvement to the accuracy of such calculations.⁴² Iterative protocols are part of most suggested procedures. Back-calculation and its applications to both protein and nucleic acid structures are described elsewhere in this Encyclopedia. Of importance in the general context is the fact that a completely correct back-calculation is not possible without detailed knowledge of the spectral density functions (correlation times) needed to describe internal motions in the

protein. Good predictions of spectra from proposed structures are possible when the structure can be taken as rigid and the spectral density functions to be the same throughout the molecule. Unfortunately, spurious agreement between calculated and observed spectra can also occur. In an iterative calculation based on inaccurate (or even wrong) values of the spectral density function, the internuclear distances (and hence the coordinates) can be adjusted until ‘the best fit’ is obtained, even though the adjusted distances would give poor agreement, and hence be judged incorrect, if correct values of the spectral density function were known. The use of time-averaged distances in the back-calculation is also not unproblematic, since molecular dynamics simulations generate predominantly averages of the first kind (around a single major energy minimum), with major conformational averaging being largely left out. With the inherent imprecision of the data, the indeterminacy of the generalized Bloch equations, and the limitations of the proposed remedies of this indeterminacy, the observation has been made on several occasions that back-calculation with existing methods does not significantly improve the ‘quality’ of the reported structures.⁴³ Although a completely rigorous test of this observation is lacking, the observation is likely to remain correct, unless, or until, back-calculations using a correct set of spectral density functions become possible and the obtainable raw NMR data become more precise.

2.1.6 Accuracy and Precision of Protein Structures Determined by NMR

Given the uncertainties and potential sources of bias in each exploration of the conformational space, with each method and each program potentially subject to its own limitations and bias, the use of combined search methods has gained wide popularity. Particularly common are protocols combining DG and RMD into a single program package (e.g. DIANA and DADAS) and those combining either DG or RMD structure calculations with the back-calculation of spectra. It is thought that the bias of each of the constituent search methods will be canceled by the other. The possibility that the errors will be additive has, regrettably, not been properly tested.

Before it becomes possible to assess the validity of individual structures calculated by any particular method or combination of methods, it is necessary to evaluate the *accuracy*, as well as the *precision*, of NMR structure calculations by a comparison of the families of structures calculated by different methods. Accuracy, in this as in other contexts, means the faithfulness of the reproduction of the ‘true’ structure and is only measurable with respect to a ‘gold standard’, i.e. a structure independently determined by another method. Precision, in its usual definition, measures the reproducibility of repeated measurements or calculations. Most of the NMR literature published to date is confused on this issue, and all too often one sees measures of precision offered as a measure of accuracy. The ‘first-order answer’—that protein structures built from NMR constraints, by whatever method, rather faithfully reproduce the main topological features of a protein molecule—can be considered to have been demonstrated beyond any doubt. An exact answer with regard to how accurate NMR structures are is more difficult to give. Only a few rigorous comparisons of the accuracy of NMR structures calculated by different methods have been made thus far.^{21,44} The principal finding is that the mean

structures calculated by different methods from the same set of data differ by an RMSD of 0.1–0.2 nm from each other and from a ‘true’ structure independently determined by X-ray diffraction. Claims that an accuracy of 0.025 nm can be achieved for NMR structures⁴⁵ were not based on a rigorous study of accuracy, but on a comparison of the relative precision of structures calculated by the same method using two different protocols. In such a procedure, the reference (‘true’) structure and the test structures are subject to the same systematic error. The calculated estimates are still estimates of precision and not of accuracy, and the claim is therefore not valid. The accuracy of NMR structures determined by now existing methods cannot be taken to be higher than 0.1–0.2 nm, although the precision of the family of structures calculated by any one method can be considerably higher (of the order of 0.03–0.05 nm). If one remembers that proteins in solution are subject to Brownian and internal motions, it is not too surprising that the family of structures reflected in the NMR data may be appreciably larger than any one particular structure calculation may show.

2.2 Solution Structures of Nucleic Acids

These can be defined by using the same procedures as for the structures of proteins. The structure determination involves the same four steps: resolution and assignment of the spectrum, derivation of geometric parameters from spectroscopic data, and model building. For reasons of resolution, limited by spectral overlap, the possibilities of NMR structure determination are for the present limited to relatively short stretches of oligonucleotides (up to 20–30 mers for double-stranded DNA). For such structures an additional serious limitation comes into play in that only short-range distances, i.e. between adjacent bases and base pairs, can be found. Long range interactions, so useful in defining the tertiary fold of a polypeptide chain, are not found in the short, rod-like structures. It is conceivable that for larger circular and supercoiled DNAs, where long-range interactions occur, they could also be detected and used, as in the case of polypeptides to define the tertiary structure. However, the resolution of the spectra of larger DNA structures is beyond the limits of current methodology. Thus only local structural features in nucleic acids—for di- or trinucleotide stretches—can, for the present, be studied by NMR. An exception is the structure of DNA fragments in complexes with proteins, exemplified by the operator–*trp*-repressor complex. In such cases the long-range interactions are provided by protein contacts, allowing the detection of longer range structural features, such as bends and twists of the double helix.

Details of NMR studies of oligonucleotide structures, of their complexes with a variety of drug molecules and of the methods developed for this purpose are given in several articles elsewhere in this Encyclopedia. A critical evaluation of the applicability of NMR methods to solution structure of nucleic acids, published in 1991 by Wemmer,⁴⁶ should be read by anyone concerned with the significance of published oligonucleotide structures derived from NMR data. In no other field of biological applications of NMR has the disregard for the principles and pitfalls of NMR structure determination outlined in the preceding section produced as much questionable, and outright erroneous, published information. A dramatic claim for the existence of highly

bent, twisted and otherwise distorted, nearly doughnut-shaped DNA segments had already been published in 1988.⁴⁷ A re-examination of the method of analysis used in these studies brings to light the danger of overinterpreting the precision of distance constraints by calibrations that do not take either spin diffusion or internal motions into account and using a global optimization procedure with a set of only local constraints. Structures calculated by such oversimplified procedures are not likely to be correct. The extent to which the use of NMR methods for studies of nucleic acid structures is meaningful has not changed since it was succinctly summarized by Wemmer: ‘Aspects of secondary structure and the general positioning of bases can be determined readily from NMR data. Highly quantitative structure analyses must be viewed as quite questionable at this time.’

2.3 Solution Structures of Noncovalent Complexes

The solution structure of noncovalent complexes (in particular DNA–protein and small ligand–protein complexes) can also be defined by the procedures described above. The only difference is that docking constraints (e.g. NOEs between the ligand and the protein or between two macromolecules) have to be used in addition to the usual set of constraints defining the geometry of each of the components. The docking constraints play a crucial role in defining both the topology of the complex and the structural changes that occur upon complex formation. For DNA–protein complexes, relatively few docking constraints will define the geometry and, where applicable, the symmetry of the complex, and identify the regions of contact. Many such constraints are required to define the fine structure of the interface and the structural changes resulting from complex formation. In the case of the operator–*trp*-repressor complex already mentioned as the largest NMR structure to have been determined so far, a considerable distortion of both the DNA and the protein structure occurs upon binding in the presence of tryptophan, so that simple docking of the independently determined operator and repressor structures using only experimental docking constraints gives only an approximate structure, although its symmetry is correct. A complete *de novo* structure determination was necessary in this case to account for all of the data in detail. The resulting structure is shown in Figure 11.¹⁶

Two considerations are of importance when viewing reported ligand–protein structures. First, several of the structures that are found in the literature are based on model building only—i.e. on rigid body docking of independently determined ligand and protein structures (in the case of DNA based on a standard B-DNA model).⁴⁸ Such structures must be regarded as hypothetical and must be distinguished from structures obtained by a bona fide complete structure determination, to which, as the *trp*-system example shows, they are by no means equivalent. Second, discrepancies between NMR structures and crystal structures of the same complex must be examined with care, as they may provide important information. In the case of the *trp*-repressor–operator complex, direct hydrogen bonding contacts between the DNA and the protein are compatible with all observed NMR constraints. In the crystal structures of the same complex, several protein–DNA contacts are mediated by water molecules, a rather unusual

Figure 11 Solution structure of the *trp*-repressor–ODNA complex. The view shows the repressor backbone with DNA at full atomic representation. (Reproduced from H. Zhang, D. Zhao, M. Revington, W. Lee, X. Jia, C. Arrowsmith and O. Jardetzky, *J. Mol. Biol.*, 1994, 238, 592)

feature even among protein–DNA complexes determined by X-ray diffraction. For the study of noncovalent complexes, NMR may prove to be the better method. In several reported cases it is apparent that flexible protein segments are involved in the interaction with DNA,⁴⁹ and flexible peptides are found at protein binding sites.^{50,51} The flexibility of such structures means that they are particularly vulnerable to the action of external forces, and specifically those that are responsible for crystallization. Whereas distortion of tightly packed covalent protein structures upon crystallization is generally regarded as minimal, this is not necessarily the case when the much weaker noncovalent complexes are examined. One should therefore expect to encounter artifacts resulting from crystallization which would not occur in the solution structure. Only a minor distortion of specific contacts is required to allow water molecules in the crystallized complex where they would not normally occur in solution, creating the potentially erroneous impression that they play a functional role.

3 MACROMOLECULAR DYNAMICS

NMR spectra are sensitive to molecular motions over a wide range of frequencies. The timescales on which each of the principal measurable NMR parameters—chemical shifts, line intensities, coupling constants and relaxation rate constants (including linewidths and NOEs), and proton exchange rates—provide dynamic information are summarized in Figure 12.⁵² The total range spans from picoseconds to hours, days and weeks, making NMR a uniquely useful method for the study of dynamic processes in molecules (as in the case of structure) at atomic resolution. Although other spectroscopic methods allow the study of dynamic processes at selected points in a protein structure, focusing on a single atom or a group of atoms, no other method allows the *simultaneous* observation of dynamic phenomena in different parts of the molecule at atomic resolution. Application of high resolution NMR to the study of proteins has led to the discovery of several types of dynamic phenomena in protein molecules, most of which are as yet not fully

understood. We can distinguish at least five categories of such phenomena: (1) variation of fast (i.e. nanosecond) motional frequencies along the polypeptide backbone; (2) enhanced conformational flexibility of longer backbone segments on different timescales (nanoseconds to seconds); (3) ‘breathing’ of folded protein made evident by the free rotation of aromatic amino acid side chains in the tightly packed core of many proteins or by rapid exchange of backbone NH protons with the solvent (micromillisecond); (4) conformational equilibria involving entire domains (usually on a millisecond to second timescale); and (5) dynamic states of partially folded structures observed under denaturing conditions. Variations of motional (rotational) frequencies along an amino acid side chain on the protein surface might be considered as a sixth category, but they are relatively well understood and of interest for the understanding of protein function only in the special cases when the motion becomes hindered by interactions.

3.1 Protein Dynamics

3.1.1 Fast Motional Frequencies along the Backbone

The possibility of resolving and assigning individual resonances for most atomic groups in the protein has brought with it the possibility of mapping the motional frequencies, which are reflected in relaxation parameters, for each individual group. Generally, a combination of relaxation parameters— T_1 , T_2 and $T_{1\rho}$, and for ^{13}C and ^{15}N atoms with covalently bonded protons, also the NOE—has to be used to define the motions of interest and their frequencies. A most exact analysis of the motions along the peptide backbone allows the direct calculation of individual spectral density functions for individual interatomic vectors from experimental data without recourse to any (always arbitrary) model for their analysis. This type of analysis does not directly define a physical picture of the motions—a motional model giving a correct prediction of the spectral density functions is required for this purpose. However, *variations* in motional frequencies and amplitudes along the backbone can be mapped, although it should be said that they are also evident from the raw relaxation data themselves, independently of any method of analysis. The experimental results reported so far reflect two types of situation: (a) relatively rigid proteins, e.g. the IIA domain of glucose permease,⁵³ for which the variation in the magnitude of measured relaxation parameters along the polypeptide backbone is minimal; and (b) proteins containing segments of varying flexibility, e.g. staphylococcal nuclease, eglinC, gal4, calmodulin⁵⁴ and others. Larger amplitude motions are frequently observed in loops and at hinges between compact domains. In some cases these motions may involve the entire loop, leading to a poor definition of the NMR structure, whilst in others they are limited to one or a few residues at each end of the loop, the remainder of the loop appearing well structured. In other cases large-amplitude motions affect a group of residues within a unit of secondary structure, as in the case of interleukin or staphylococcal nuclease. There is as yet no clearly recognizable pattern to the distribution of amplitudes and frequencies of these fast motions, and it is not yet clear whether they play any role in protein function or are irrelevant byproducts of protein architecture.

Figure 12 Timescales in seconds defined by NMR parameters. (I) Region of fast exchange; (II) region of intermediate exchange; (III) region of slow exchange. (Reproduced from O. Jardetzky and G. C. K. Roberts, 'NMR in Molecular Biology', Academic Press, New York, 1981)

The interpretation of the observed spectral density functions in terms of motional parameters, i.e. amplitudes and frequencies, depends of course on the construction of an appropriate model. Such models are necessarily complex and are only now beginning to emerge. The models used initially—anisotropic rigid body rotation, fast rigid rotor on a slower rigid rotor, wobbling on a cone^{55,56}—were too simplistic to account for more than a few data points. Model-free approaches, which have enjoyed some popularity, can generate detailed motional maps, but fail to provide a complete insight into their nature. The original model-free approach of King and Jardetzky⁵⁷ can account for the observed motional frequencies, but not for the detailed amplitude characteristics of the motion. The model-free approach of Lipari and Szabo⁵⁸ actually represents a very restrictive model, equivalent to rigid body rotation with one degree of internal motional freedom or a two-term expansion of the King–Jardetzky formalism. Not surprisingly, it fails to account for the more detailed motional maps now obtainable experimentally,⁵⁹ just as any other of the oversimplified models. In the experimental maps, one can frequently see regions affected by slower motions of some kind, largely reflected in anomalous values of T_2 . No fully satisfactory treatment of such slow motions has as yet been developed, although it has been suggested that they represent concerted motions, such as solitons.⁶⁰ Molecular dynamics simulations have shown promise in accounting for fast rotations in protein side chains.⁴² Their great attraction is that they allow an independent, rigorous, a priori calculation of spectral density functions, which can then be compared with those obtained from experiments. In principle, molecular dynamics can provide a complete explanation of all dynamic processes observed in proteins, including the slower (micro- to millisecond) motions. Unfortunately for the nanosecond and slower motions observed along the backbone, rigorous molecular dynamics simulations are not yet practical. A complete and correct description of the patterns of the motions observed along the polypeptide chain

remains a subject for future research, as does the evaluation of their functional significance.

3.1.2 Conformational Flexibility

Conformational flexibility of a longer contiguous segment of the peptide backbone may occur on any timescale and can be reflected in a different set of NMR parameters in different cases. Many examples of flexible segments varying in length from 7 to 25 or even more amino acid residues are now known. Some occur at the *N*- and *C*-terminals of peptide chains and some in their interior. The earliest discoveries of flexible segments—those of the RNA-binding site in Tobacco Mosaic Virus (TMV),⁶¹ the DNA-binding domain of the *lac*-repressor,⁶² histones,⁶³ and the S1 domain of myosin⁶⁴—were based on the finding of anomalously narrow lines (long T_2) reflecting free rotation on a nanosecond timescale. In the crystal structure of TMV the corresponding segment was found to be disordered. In the more recent examples—the DNA-binding domains of the *trp*-repressor⁶⁵ and antennapedia homeodomain,⁶⁶ and the B-chain of insulin analogs⁶⁷—fast motions do not play a prominent role, and the most striking finding is the absence of NOEs needed to define the structure of the segment. This finding is usually accompanied by the finding of unusually rapid exchange rates for the peptide backbone protons. Structure calculations on molecules containing such segments lead to the conclusion that the segments are disordered in solution. However, the apparent disorder may reflect averaging between two or more well-defined conformations. In the absence of line narrowing and other anomalies in the relaxation parameters, the conclusion must be drawn that the conformational averaging occurs on timescales longer than nanoseconds. In favorable cases, where the segment undergoes transitions between a closed and an open form of a secondary structure (e.g. a helix-coil transition), the rates of conformational averaging can be estimated from rates of backbone proton exchange. A very detailed study

of conformational flexibility in the DNA-binding domain of the *trp*-repressor has led to the conclusion that the interplay of dynamic processes in peptide segments can be quite complicated. It is thus necessary to distinguish between *true flexibility*, or *true disorder*, and *apparent flexibility*, or *apparent disorder*. In the case of true flexibility one will find ‘random coil’ behavior by all NMR criteria—rapid averaging of chemical shifts and coupling constants, rapid proton exchange and rapid motions reflected in narrow lines, as well as disappearance of NOEs and other cross peaks in multidimensional spectra. These are findings typical of the N- and C-terminal peptide segments in several proteins. On the other hand, in cases of apparent disorder or flexibility the findings tend to be contradictory, as they are in the case of the *trp*-repressor. The DNA binding segment appears disordered if one relies on the observations of sequential NOEs, backbone proton exchange rates and backbone ^1H T_1 measurements. At the same time, it appears ordered from the ^{15}N relaxation profile and from the finding of α -CH shifts typical of α -helical structures. The findings can be reconciled if one infers that the segments are largely helical on a nanosecond timescale, but the helices are unstable on longer (in this case millisecond) timescales, and the closed state (corresponding to the formation of a hydrogen bond) at all sites exists less than 100% of the time. One is thus dealing not with a continuum of conformational states, which defines true flexibility, but rather with a structure that is unstable and hence ‘flexible’ only on a much longer timescale. A similar phenomenon is known to occur in the ready unfolding of the *lac*-repressor DNA-binding domain. In this case sufficient NOEs were found initially to define a helical structure, but the structure was shown to be unstable under a variety of ambient conditions.⁶⁸

The quantitative analysis of the apparent disorder cases requires a wide range of NMR measurements and can be rather complicated. Selective attention to only some of the NMR parameters (e.g. only the set of observable NOEs, which has become common practice in NMR structure determination) will confuse true and apparent disorder and lead to erroneous conclusions, as will the uncritical application of commonly used theoretical treatments [e.g., those for backbone proton exchange, which are based on simplified assumptions of relatively stable secondary structures (see *Hydrogen Exchange and Macromolecular Dynamics*), and do not apply in the general case]. The paradigm for the analysis of the general case was first worked out for the *trp*-repressor and is briefly summarized here because of its wide applicability. The picture of the repressor helix–turn–helix DNA-binding domain that has emerged from this analysis is as follows: the region consists of two helices which retain their overall helical shape at all times, but with hydrogen bonds opening, one at a time, on a millisecond time scale.

Three types of experiment are necessary to calculate the exchange rates (or lifetimes) between the different states in this type of situation. First, the classical hydrogen–deuterium exchange experiments can identify hydrogen bonds that are stable on timescales from minutes to years. Second, proton T_1 relaxation, with and without solvent presaturation, will identify those hydrogen bonds undergoing an exchange on a millisecond to second timescale. Third, the pH dependence of the T_1 will allow calculation of opening and closing rates, since the intrinsic exchange rate is known to be pH dependent and can be independently evaluated from the amino

Figure 13 The generalized Linderstrøm–Lang model

acid sequence (see *Hydrogen Exchange and Macromolecular Dynamics*).

The simplest model that can account for the observation is the generalized Linderstrøm–Lang model, which is free of all of the usual assumptions about the relative magnitudes of helix opening, helix closing and intrinsic exchange rates^{69,70} (Figure 13). The magnetization transfer equations describing this model without arbitrary simplification are the generalized McConnell equations:

$$\left. \begin{aligned} \frac{dM_A}{dt} &= -R_{1A}(M_A - M_A^{\text{EQ}}) - k_{\text{open}}M_A + k_{\text{close}}M_B \\ \frac{dM_B}{dt} &= -R_{1B}(M_B - M_B^{\text{EQ}}) + k_{\text{open}}M_A - k_{\text{close}}M_B \\ &\quad - k_{\text{intr}}M_B + k'_{\text{intr}}M_{\text{H}_2\text{O}} \\ \frac{dM_{\text{H}_2\text{O}}}{dt} &= -R_{1\text{H}_2\text{O}}(M_{\text{H}_2\text{O}} - M_{\text{H}_2\text{O}}^{\text{EQ}}) - k'_{\text{intr}}M_{\text{H}_2\text{O}} + k_{\text{intr}}M_B \end{aligned} \right\} \quad (15)$$

whose solution is:

$$\begin{aligned} M_A &= C_1e^{\lambda_1 t} + C_2e^{\lambda_2 t} + C_3 \\ M_B &= D_1e^{\lambda_1 t} + D_2e^{\lambda_2 t} + D_3 \end{aligned} \quad (16)$$

The symbols are defined in the Appendix at the end of this article.

The solution of these equations predicts pH independent single exponential behavior for the NHs of slowly exchanging (stable) hydrogen bonds, and pH dependent double exponential behavior for hydrogen bonds exchanging on a timescale comparable to the intrinsic relaxation rate, T_1 (milliseconds to seconds).^{71,72}

In the study of the pH dependence of relaxation in the *trp*-repressor, the observation was made that, even though the data could be accounted for by this model, the conclusions drawn about the percentage helicity and opening and closing of helices were contradicted by other experimental findings. The contradictions are summarized in Table 2.

To account for all the data simultaneously, one either has to assume that the ‘open’ state in the Linderstrøm–Lang model is not completely open, characterized by $k_{\text{intrinsic}}$ slower than the rate observed in a free peptide, or alternatively, invoke a three-state model allowing for the observed slow exchange between

Table 2 Contradictory Evidence on the Percentage Helicity and Opening and Closing of Helices

Helix–Coil Transition	Process Monitored by T_1
$\geq 90\%$ helicity (δ , ^{15}N)	20–40% ‘helicity’
$k_{\text{ex}} > 100$ Hz ($\Delta\delta$, temperature dependent)	$0.4 < k_{\text{ex}} < 4$ Hz

Figure 14 The three-state model

'locked' and 'unlocked' states of the DNA-binding helices, and a rapid helix–coil equilibrium (Figure 14). The equations for this model, too complex to be reproduced here, reduce to the form of equations (15) and (16) if the helix–coil equilibrium is rapid. The physical meaning of the observed rates is, however, in either case different than that originally envisioned. This underscores the importance of comparing different types of NMR and other data if one is to arrive at a correct description of solution structures and their dynamics.

The functional significance of segmental flexibility—either true or apparent—may well be to facilitate conformational adjustments on binding to ligands. It is probably no accident that segmental flexibility appears prevalent in the binding domains of DNA (and RNA) binding proteins. Especially in the case of repressors, such as the *trp*-repressor, which are known to interact with more than one DNA sequence, such conformational flexibility could be necessary to make the optimal contacts in each case, using the same amino acid sequence and the same secondary structure. Similarly, in the case of insulin, flexibility of residues 20–30 in the B chain could facilitate conformational adjustments upon receptor binding. A very interesting example of flexibility associated with the ability of a segment to assume a helical conformation in the crystal and a β -turn conformation in solution has been described for chicken egg-white cystatin.⁷³ The function of this segment is as yet unknown, and much remains to be learned about protein function from the NMR study of similar phenomena in other proteins.

3.1.3 'Breathing' Motions

Breathing motions first became apparent in the spectra of selectively deuterated staphylococcal nuclease, which showed that the tyrosines in the interior of the molecule had motionally averaged spectral lines.⁷⁴ This phenomenon was extensively studied on several proteins in the 1970s, and the rates for the 180° flip were estimated to lie between 102 and 104 s⁻¹. A temperature dependent transition from the 'frozen' configuration at low temperatures to the freely rotating state at room temperature was described for ferrocycytochrome C.⁷⁵ In the case of parvalbumin, low amplitude librations of phenylalanine rings in the core on a nanosecond timescale, detectable by ¹³C relaxation, could be shown to precede the relatively rare 180° flips on a microsecond timescale, evident from chemical shift averaging.⁷⁶ Rotation of rings in the interior of the protein has been and always needs to be considered in the interpretation of NOEs used for a protein structure determination.¹⁸ The

relationships of such 'breathing' motions to backbone motions and segmental flexibility have not yet been sufficiently studied, but it may be expected that they will emerge from comparisons of the relative timescales, directions, and amplitudes. Ideally, the relationship should be given by molecular dynamics calculations, but molecular dynamics simulations on the required micromillisecond timescales are impractical at present.

3.1.4 Conformational Transitions

Conformational transitions usually manifest themselves as changes of local structure. The ease of detecting and describing them depends on the lifetimes of the conformational states involved. If the exchange between the states is slow on the chemical shift timescale, i.e. the lifetimes of the states are long compared to the inverse of the chemical shift difference between the peaks representing the two states, the states can be observed and described separately by standard structure determination methods. Into this category fall the conformational readjustments occurring in Ca²⁺ binding proteins upon addition of Ca²⁺, which have been studied extensively and are described elsewhere in this Encyclopedia, and many others. If the exchange rate is of the same order as the frequency difference of chemical shifts between the two states, the transition is often observable as a selective line broadening. The early NMR detection of conformational equilibria, even in simple enzymes such as pancreatic ribonuclease A,⁷⁷ was based on this phenomenon. As the exchange rate becomes more rapid on the chemical shift timescale, the individual conformational states can no longer be resolved. In the intermediate exchange range it is possible to infer from the data that an exchange process is occurring, but not the nature of the conformers or their number. In the rapid exchange case, even the existence of the exchange process itself is not directly detectable. This leads to the well-known problem that a structure determination on a system undergoing rapid averaging between two or more distinct conformations leads to a structure that has no physical meaning.^{52,78} Attempts to resolve this dilemma by modeling the individual conformers and calculating the pattern of NMR parameters that would correspond to a dynamic average of the multiple states have been published.⁷⁹ A residual of uncertainty as to the adequacy of the dynamic model invoked will always remain for structures determined on systems undergoing conformational averaging. In formulating and testing such a dynamic model, it is therefore advisable to invoke a wide range of NMR experiments and test the interpretation of results for internal consistency.

3.1.5 Dynamic States of Partially Folded Structures and the Problem of Protein Folding

These topics are an active area of current research, and NMR approaches to this problem are discussed in detail elsewhere in this Encyclopedia. Suffice it to say here that studies of this type—conducted on objects known to be unstable—are especially vulnerable to the problems of conformational averaging discussed above. At the same time, it must be pointed out that even NMR 'structures' of intermediates which have no physical existence ('apparent structures') may be useful as indicators of the trends of changes occurring in

the structure as it folds or unfolds, respectively, and thus point to the deciphering of the folding pathway. An interesting recent example has been provided by the work of Dobson and coworkers⁸⁰ on the folding pathway for the assembly of hen egg-white lysozyme. The pathway appears to proceed from: (1) the formation of α -helices; to (2) the formation of two-helix bundles; to (3) the addition of a β -structure to form a 'molten globule' that topologically resembles the final structure, but is not well defined in detailed contacts and must undergo a rearrangement to yield, (4) the fully folded lysozyme.⁷³ A caveat emerging from this study is that alternative pathways are also compatible with all of the available NMR data. This reflects the ambiguity of the NMR data, but may also reflect the actual existence of multiple folding pathways. In a case of this kind, extensive correlation of the NMR findings with findings obtained by other physical methods is essential for the resolution of ambiguities.

3.1.6 Implications of Internal Motions and Flexibility for Structure Determination by NMR

The most serious problem to be considered when deriving solution structures of proteins from NMR data is that of conformational averaging, as discussed above. The problem is ubiquitous, and the burden of proof that the reported structure is rigid as calculated, remains on the investigator. For small compact globular proteins the problem is minimal. Averaging in a single potential well around a single set of coordinates is, for all practical purposes, indistinguishable from the case of a rigid structure, and corrections for this type of averaging have been proposed.⁴² Short disordered regions are easily detected by the absence of NOEs, as in the case of insulin. The problem is much more serious for larger proteins, where averaging between ordered local structures may occur, as in the case of the *trp*-repressor. In such cases a detailed study of the dynamics becomes necessary, before the proposed structure can be given full credence. As has been pointed out already, many years ago,^{23,78} to derive correctly a protein solution structure from NMR data, it is necessary to understand the dynamics of the protein in detail, and vice versa. Simple NMR structure determination is limited to simple objects. For most proteins, the study of structure and dynamics must, of necessity, go hand in hand.

3.2 Nucleic Acid Dynamics

Two types of rapid motion are known to occur in nucleic acid structures: (1) puckering of the phosphate backbone, reflected in the rapid averaging of ³¹P chemical shifts so that typically, with few exceptions, only a single phosphate NMR signal is observed in both short oligonucleotide double helices and long (300–600 base pair) stretches of DNA; and (2) puckering of the sugar rings (deoxyribose in DNA and ribose in RNA, respectively), usually described as an exchange between a 2'-*endo* and a 3'-*endo* conformation.⁸¹ Since the exchange rate is rapid on both the chemical shift and the coupling constant timescales (so that only time-averaged parameters are observed and individual states can not be resolved), it remains possible, but unprovable, that the exchange involves more than two states. Both of these motions clearly reflect thermal fluctuations. If they have any

functional significance, it is to reflect the inherent flexibility of nucleic acid strands, necessary for the unwinding of double-stranded structures in the processes of replication, transcription and translation. It has been proposed that these motions may be accompanied by changes in helical twist.⁸² On the other hand, wobbling of bases in double-stranded structures is rarely of sufficient amplitude to be reflected in NMR parameters, except at the fraying ends of oligonucleotide sequences.⁸³ Motions within the DNA double strand can be modulated and damped by the binding of intercalating agents. For purposes of structure calculations, short double-helical oligonucleotide strands can be treated as if they were rigid, since all of the described motions result only in averaging about a single energy minimum, i.e. within a single potential well. As yet, insufficient NMR data on the structure and dynamics of RNA are available to judge whether the more complex RNA structures found in crystallographic studies also undergo more complex and functionally significant motions. The existence of such motions can for the present only be inferred from the diversity of binding and catalytic interactions within the RNA family, observed in biological experiments. Conformational flexibility is a prerequisite for such diversity. Specific examples of nucleic acid dynamics are discussed elsewhere in this Encyclopedia (see *Nucleic Acids: Spectra, Structures, and Dynamics*).

4 MOLECULAR INTERACTIONS

Molecular interactions of small ligands with macromolecules were among the first biological problems to be successfully studied by NMR. As early as 1961 a relaxation method for the determination of the groups involved in ligand–protein interactions had been developed in the author's laboratory.^{84,85} With the methods then available, it was possible to infer which part of the flexible ligand—e.g. the phenyl ring of penicillin, rather than the penicillanic acid moiety—was bound to the protein. Interesting observations on different modes of binding in the sulfonamide family could be made, distinguishing binding by the sulfonamide ring from binding of an aromatic substituent to the same protein.⁸⁶ Later, it became possible to infer structures of inhibitor binding sites from a combination of NMR observations of ligand and protein side chains, as in the cases of pancreatic ribonuclease⁸⁷ and staphylococcal nuclease.⁸⁸ The binding of a transition state analog to lysozyme was also the subject of one of the early studies.⁸⁹ With modern technology it is possible to obtain detailed structures of binding sites, even for proteins that are for the time being too large to be amenable to a complete structure determination. A classic example is the detailed study of the binding of substrates and cofactors to dihydrofolate reductase, carried out by Roberts and coworkers.⁹⁰ In these studies it was found, long before a complete structure determination, that the cofactors NAD and NADH bound in different orientations, and, in a corresponding study of the dynamics, that the bound heterocyclic rings were able to undergo 180° flips in the bound state. A similar detailed study of the anti-TEMPO hapten antibody Fab fragment binding site by McConnell and coworkers⁹¹ revealed that hapten binding caused a conformational change involving the displacement of a tyrosine side chain near the binding site to accommodate the hapten moiety. A detailed NMR structure of the Fab

fragment is not yet available. A complete structure of the tryptophan binding site in the *trp*-repressor was obtained in the course of the structure determination. It must be said, however, that the precision with which noncovalent structures can be defined from NMR data still leaves something to be desired, although the general configuration of the complex can be clearly outlined and the possibilities of forming different contacts evaluated. In dynamic NMR studies of ligand-protein interactions, the lifetimes of the bound and free states and the binding constants can be estimated. For typical small molecule ligands, the dwelling time on a protein falls in the millisecond range.

NMR studies of binding sites are particularly attractive when a comparison of the binding modes of different ligands (e.g., in a series of analogs) are needed, because of the relative speed and efficiency with which comparisons can be made. For ligands binding in a similar manner, the spectral changes (e.g., in the observed NOE pattern) from one compound to the next will be minor, and similarity of binding can be inferred from the similarity of the spectra without a complete reanalysis of the spectra in each case. Only when the binding patterns are different will the spectral changes be marked and require a de novo interpretation. A further advantage of NMR studies in this context is that comparative kinetic information on the exchange rates between the bound and free states is readily obtainable.

5 PROTEIN FUNCTION

Studies of protein function made possible by NMR fall into several categories. Very few detailed studies of this kind have as yet been carried out, but the possibilities have been clearly recognized.

The function of enzymes can be studied at several levels. Rates of enzymatic catalysis can be followed by observing the disappearance of substrates and appearance of products in (real) time. Structures of enzyme-inhibitor, enzyme-substrate or enzyme-transition-state analog complexes can be determined and examined for clues concerning the involvement of different groups at the binding site in the process. The first successful example of such a study was that of pancreatic ribonuclease A,^{77,87} leading to a proposed mechanism that has since been confirmed by several kinetic and structural methods. Conformational changes and conformational equilibria involved in allosteric regulation can be defined, as described above. The obvious advantage of NMR over X-ray diffraction in this context is that the enzyme can be studied in its natural environment in solution, and that the dynamic processes involved can in many cases (though not always) be observed directly rather than being inferred from the initial and final states that can be crystallized.

The function of regulatory proteins, in which points of contact between the protein and DNA can be altered by a small molecule ligand, can be examined in much the same way as the function of allosteric enzymes. The study of the operator-*trp*-repressor complex, which forms in the presence of tryptophan and dissociates in its absence, can serve as the prototype for all studies of this type. This system is not only, as already noted, the largest molecular entity determined by NMR, but also the only complete allosteric regulatory complex analyzed by NMR methods in detail. All other NMR studies of protein-DNA interactions that have been reported involve binary complexes between the two macromolecules, with the regulatory function and ligand binding sites having been lost in the preparation of DNA-binding domains small enough to be easily studied by NMR. Structural studies of the complete system, including the ternary ligand-protein-DNA complex revealed a first conformational change on corepressor tryptophan binding and a further conformational change on the formation of the ternary complex with operator DNA. Dynamic studies revealed a stabilization of the DNA binding region by the binding of tryptophan and a further stabilization upon the formation of the ternary complex. The actual process is therefore more complex than the simple model commonly used for regulatory proteins—a single ligand induced conformational transition which aligns the DNA binding sites for better docking. It is to be expected that further, as yet unanticipated, variants of regulation by structural change will be uncovered in the course of studies on other systems.

Proteins involved in signal transduction and information transfer are also thought to function by undergoing structural transitions and, therefore, can be studied by the same techniques as those applied to the *trp*-repressor system, as can transport proteins functioning by an allosteric mechanism.

6 CONCLUSIONS

In summary, it can be said that the biological-NMR literature to date has laid all the necessary foundations for the study of protein structure, dynamics, interactions and function, devising and testing the required techniques and prototype experimental protocols on selected prototype systems. To a lesser extent, this can also be said of nucleic acids. Some technical development still remains to be done, in particular testing combinations of techniques to solve specific problems. The full range of potential applications remains in the future.

7 APPENDIX: DEFINITION OF SYMBOLS USED IN EQUATION (16)

$$\lambda_1 = \frac{-\frac{1}{T_{1A}} - k_{\text{open}} - \frac{1}{T_{1B}} - k_{\text{close}} - k_{\text{intrinsic}} + \sqrt{\left(\frac{1}{T_{1A}} + k_{\text{open}} - \frac{1}{T_{1B}} - k_{\text{close}} - k_{\text{intrinsic}}\right)^2 + 4k_{\text{close}}k_{\text{open}}}}{2}$$

$$\lambda_2 = \frac{-\frac{1}{T_{1A}} - k_{\text{open}} - \frac{1}{T_{1B}} - k_{\text{close}} - k_{\text{intrinsic}} - \sqrt{\left(\frac{1}{T_{1A}} + k_{\text{open}} - \frac{1}{T_{1B}} - k_{\text{close}} - k_{\text{intrinsic}}\right)^2 + 4k_{\text{close}}k_{\text{open}}}}{2}$$

$$\begin{aligned}
 C_1 &= \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) \left\{ \frac{(M_A^i - C_3) \left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) - k_{\text{close}}(M_B^i - D_3)}{\left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \right\} \\
 C_2 &= k_{\text{open}} \left\{ \frac{(M_B^i - D_3) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}(M_A^i - C_3)}{\left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \right\} \\
 D_1 &= k_{\text{close}} \left\{ \frac{(M_A^i - C_3) \left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) - k_{\text{close}}(M_B^i - D_3)}{\left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \right\} \\
 D_2 &= \left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left\{ \frac{(M_B^i - D_3) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}(M_A^i - C_3)}{\left(\lambda_2 + \frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\lambda_1 + \frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \right\} \\
 C_3 &= M_A^{\text{EQ}} + \frac{f k_{\text{close}}}{\left(\frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}} \\
 D_3 &= M_B^{\text{EQ}} + \frac{f \left(\frac{1}{T_{1A}} + k_{\text{open}} \right)}{\left(\frac{1}{T_{1A}} + k_{\text{open}} \right) \left(\frac{1}{T_{1B}} + k_{\text{close}} + k_{\text{intrinsic}} \right) - k_{\text{open}}k_{\text{close}}}
 \end{aligned}$$

For presaturation experiments: $f = -k_{\text{intrinsic}}M_B^{\text{EQ}}$. For no-presaturation experiments: $f = 0$.
